ON THE HEALING OF TUBERCULOSIS
(CLINICAL FEATURES).*

BY HERBERT MAXON KING, M.D.,
LIBERTY, N. Y.
PHYSICIAN TO THE LOOMIS SANATORIUM.

THE work of Naegeli, Franz, and others showing the apparent almost universal diffusion of tuberculosis, at least among the residents of more thickly populated communities, has necessarily somewhat modified our views with regard not only to the distribution and curability of the disease, but to its etiology and history, and especially to the clinical features characterizing its onset, progress, and decline.

It seems to be a reasonable and certainly a growing conviction that practically all who reach 20 or 30 years of age have become infected and harbor in some obscure corner of the organism latent tuberculous foci lacking only suitable conditions to spring into activity. That tubercle bacilli effect anatomical changes sufficient to be recognized post-mortem would imply that at some time subsequent to the infection there must certainly have been an active lesion, however minute and whether or not clinically demonstrable. Thus, in a sense, practically every apparently healthy adult is, after all, but an arrested case of tuberculosis. It seems probable that if our knowledge of the etiology and early history of the development of the disease were more accurate, or, in other words, if we were able to differentiate decisively early and obscure foci of tubercle from a hundred other causes of slight departures from the normal, we should find at some time in the early life of nearly every individual that clinical evidence which would support the startling and almost sensational announcements from the autopsy chamber.

It is inconceivable that tubercle formation can progress to a point histologically recognizable without, to some extent, disturbing metabolism at least temporarily. Undoubtedly there is always an attending symptomatology, which, so far, we have failed to identify from clinical indications of other and comparatively insignificant disturbances. I cannot doubt, however, that tubercle formation, however remote from vital organs and however circumscribed in area, must give rise to distinctive clinical features, which an improved technique in diagnosis and, what is of greater importance, a more comprehensive knowledge of the disease shall enable the clinician to recognize.

If, then, we accept the conclusions which seem unavoidable from such experience as that of Naegeli, which we may do, at least tentatively and for the sake of argument, remembering always Adami's invaluable protest against accepting half-truths for whole truths, the old question once more arises why, if all are subjected to the infection, does the vast majority escape and only a comparatively small proportion develop a recognizable tuberculous lesion? Here we are almost forced to take refuge in what we might term Dr. Osler's parable: "The seed falls on stony ground," and the reason why tubercle does not go on to clinically recognizable lesions in those who escape lies in the unsuitability of the soil. But was the soil unsuitable *before* infection? Apparently not, for we find at the post-mortem even in these individuals unmistakable evidence of past or present lesions which seem to prove, in just so far as they have progressed, the degree of inhibitive immunity which the individual had acquired by the vaccination process of tubercle formation.

Both clinical and pathological experience indicate that there is a tendency to prompt reactionary phenomena on the part of the infected organism—that there is a tendency from the beginning toward limitation and healing of the tuberculous focus. It would, however, appear as hardly probable in the light of present views on immunity, that there is at birth an appreciable difference in susceptibility between individuals, unless we accept the theory of inherited predisposition or inherited immunity as the case might be. This seems true, at least so far as tuberculosis is concerned, since practically all carry the lesion or its scar as an evidence of original susceptibility. Those who have never given recognizable clinical evidence, therefore, are the fortunate ones whose physical condition at the time of the infection was such as to permit of the most immediate and sufficient production of antibodies in the blood and protective tissue changes at the seat of the lesion. In the unfortunate minority it is fair to suppose that either an increased quantity or virulence of the infecting virus or a lowered vitality (acquired) on the part of the infected organism is responsible for the appearance of distinctive clinical features of tuberculosis.

This, I am aware, is a digression, but as the clinical features of a healing lesion are chiefly concerned in the remission and disappearance of the symptoms which attended the development of the disease, and as these symptoms can so frequently be traced far back of an interval of comparative health to a period remote from the date of supposed onset of the disease, it seems desirable that we should make an effort to discover, if there be not clinical features attending tubercle formation in that class of individuals not recognized as tuberculous, and analyze these features, if they are found to exist.

With this end in view a painstaking and exhaustive inquiry into the past history of a tuberculous invalid is often full of surprises. One feature, for instance, recurs with such persistent frequency that it merits some attention; this is the striking difference in time between the first presumptive evidence of disease and the first demonstrable evidence, which is often a period of many years marked by apparently perfect health, so that at the onset of the recrudescence the original outbreak has been forgotten by the patient or regarded as having no relation to present trouble. During this interval the patient is supposed neither to have nor to have had tuberculosis, yet the subsequent development of demon-

* Read at a meeting of The Lænnec Society for the Study of Tuberculosis, Johns Hopkins Hospital, Baltimore.

strable evidence justifies the presumption that a potential disease focus existed from the start, and was during the healthy interval merely in a state of arrest. Thus, it not infrequently happens that a history of the present attack and a physical examination of the chest justify a diagnosis of incipent tuberculosis, whereas a further inquiry into the past history shows the case to be one of recrudescence of a healed or arrested lesion.

More often than is supposed the real incipiency of the disease is marked by sharp constitutional disturbance. Indeed from clinical experience one might reasonably conjecture that such a reaction on the part of the organism were essential to the healing of the focus and the production of an immunity and to look with serious suspicion upon the supposedly ideal incipient case, where physical signs in the chest are very slight and constitutional disturbance *nil,* yet with scattered bacilli in the sputa.

Will you pardon an illustration in point? A few weeks ago a patient was admitted to the sanatorium who presented the appearance of as perfect a specimen of robust health and muscular development as can well be imagined. Three weeks prior he had consulted his physician because of chills and fever following violent exertion. Slight apical lesions with very little activity were discovered. The patient casually remarked that he had never been really sick, and weighed more than ever before in his life. There were a few bacilli demonstrable in the very scant expectoration. Appearances certainly seemed to point to this case as incipient, or at least as of very recent origin, and yet the very fact of the absence of constitutional symptoms, showing no little degree of immunity on the part of the patient, suggested a longer duration of disease than was otherwise indicated. The following history, which it seems to me is very instructive, was elicited:

The patient was the first child of healthy parents, who are still living. He was said to be a sickly child. Had measles, mumps, pertussis, and chickenpox before 11 years of age, when he was taken abroad and placed in a boarding school in Vevey, Switzerland. There outdoor athletic sports formed a part of the curriculum. His health and strength greatly improved, and at 14 years he was brought home and placed in a boarding school near Boston, where he continued outdoor exercise (football and later rowing). "German measles," with subsequent catarrhal affection of the throat, occurred at this time. At 18 years he weighed 150 pounds. In 1896, at 19 years, he entered upon his university course at Harvard, weighing 168 pounds. He went in enthusiastically for football and rowing, and was evidently overtrained during his freshman year, losing considerable weight. Appetite and digestion failed, and he was treated for "stomach trouble." During the summer vacation he recovered weight and general health.

The following three years of his university life were not marked by sickness, although he always complained of digestive disturbances during the periods of hard physical training, and remembers having a more or less constant cough at such times. After graduation, in 1900, he spent a year in a manufacturing business, which admitted to a great extent of an outdoor life. In 1901 he entered a banking house, and was much more confined. He still spent his leisure hours in the pursuance of outdoor sports, especially rowing. Within a few months, however, he noticed a recurrence of the hacking cough, which now was attended with expectoration, but, as his general health and weight were unaffected, he paid no attention to the symptoms.

In July, 1904, an unusual exertion (rowing in a scull race) was followed by a severe chill, and probably fever, although he saw no physician and continued his exercise. In September he noticed chill and fever, the latter reaching 102° F. on one occasion, after very violent exertion. Finally, toward the last of September, he sought medical opinion, and was found to have tuberculosis.

There are many interesting questions suggested by such a clinical history, and some which, I think, are not irrelevant to our present purpose. We have here a patient to outward appearance in robust health, yet with indutiable evidence of pulmonary tuberculosis. The present entire absence of constitutional symptoms, together with a history of very suspicious, though vague, attacks, recurring at intervals since 1896, a period of eight years, seem to indicate that the disease is not of recent origin. If we were to accept v. Behring's conclusions, it would require no great stretch of imagination to trace the original infection to the sickly period of his infancy or early youth. But, without going so far, we may safely place the first presumptive evidence of disease at least three or four years prior to the examination. During this time we have a record of a more or less constant struggle between the bacillus and the organism. Injudicious physical overtraining, and possibly temporary interference with nutrition as a consequence or concomitant, have invariably been attended with or followed by the reappearance of certain symptoms. These, however, do not assume definite meaning until the patient gives up in part his life in the open for one of office confinement.

Ever since the infection occurred then, whenever this may have been, there have been repeated, partially successful, attempts on the part of the resisting forces of the organism to eradicate the disease. There have been periods of apparently perfect health, when unquestionably the disease was under complete arrest, only to reappear, however, when the defense was, as it were, weakened for the moment by excessive expenditure of energy and interference with nutrition, requiring of the body cells, so to speak, increased work on decreased rations.

The history of this one patient presents numerous instances of "recovery" from tuberculosis, for I think we may so regard each rebound after the several attacks. Furthermore—and I would not have you think me pessimistic if I express the opinion—these recoveries were perhaps as complete as are ever achieved in tuberculosis. It is, of course, impossible of demonstration, but fair to suppose, that if this patient had been made aware of the nature of his disease and had intelligently governed his future actions and environment accordingly, let us say at the time of his first supposed overtraining in 1896-97, there would not have been a recrudescence, and he would have been well to-day, *i.e.* he would have presented no demonstrable evidence of disease.

Will you forgive me if I cite one more case bearing on this point? In this instance unusual facilities obtained for getting accurately at dates and facts and the history has a proportionately greater value. The patient was the first child of healthy parents, still living, born a full term, weighing five pounds, was breastfed, and grew rapidly. He was perfectly healthy until taken from the breast at one year of age. From this time until after dentition he was subject to digestive disorders; he had "gastritis" at three years of age. After dentition he became healthy and strong. Had measles at seven years, chicken pox and mumps a short time after. He remained well thereafter until 1900, when he had "jaundice." He was then 21 years old and in college at Harvard. This attack, which was attended with

fever, confined him to bed for three weeks. Convalescence was slow, but apparently complete.

Graduating in 1901, he left Boston in June, and spent four months prospecting for ore north of Lake Superior. The party at first consisted of an instructor and three students, a cook, and a canoeman. One of the students had a cough and expectoration. All slept side by side in a tent. In August the patient left this party to make up another of his own, consisting of himself and three Indian half-breeds. They proceeded north nearly to Hudson Bay. As in the former case, the party occupied a single tent and slept side by side. The youngest half-breed coughed and expectorated, and was said to have had consumption (much of the preparation of the food was left to this man).

The actual physical labor involved in this expedition was severe. The marches were long and toilsome, and the patient frequently carried on his shoulders more than his own weight over long "carries." He returned to Boston in October apparently in robust health. A few days afterward, however, he developed an acute pleuritis with effusion, and was in bed for three weeks. The lung was said not to have been affected. Recovery was apparently complete, and before January, 1902, he was in better health and weighed more than ever before in his life. In July following he went to Pueblo, Colorado (altitude, 5,000 feet), as chemist for a mining company, still apparently in perfect health. He was now closely confined to the laboratory and much exposed to the fumes of chlorine, bromine, and sulphuric acid. Three weeks later he was transferred to a mine in Mexico, where the altitude was somewhat greater; here he reports "catching cold," and cough, expectoration, and slight hæmoptysis followed; but, although the cough and expectoration continued, he did not seriously regard them until April, 1904, when he was transferred to Leadville (altitude 10,500 feet). Here the symptoms increased, and finally compelled his return to Boston in October. It is, of course, unnecessary to say that extensive structural changes were plainly evident in the lungs at this time; that and subsequent events in this case do not for the present concern us. The interesting points, it seems to me, are (*a*) the source and date of the infection; (*b*) the earliest clinical manifestations of the disease; (*c*) the phenomena attending the first prompt and apparently complete arrest of the disease, and the causative factors of recrudescence.

(*a*) As to the source and date of the infection, if one wished to support a theory, and that theory happened to be v. Behring's, there would be a temptation to take as sufficient evidence of infection the digestive disturbance and "gastritis" which occurred during the cow's milk drinking period coincident with dentition, but I think for present purposes we may pass over that incident, as well as the attack of jaundice during his college life, and with propriety consider the patient to have been healthy and without tuberculous infection when he left Boston for the camp life and hard, manual labor of his prospecting enterprise in the Northwest. Here, at least, we have a very plausible history of exposure to infection from close contact with two probable, coughing consumptives extending over a period of several months. Incidentally, it is interesting and somewhat surprising to discover that infection may occur even while one is living day and night in the open air in the wilderness and in an ideal climate if individual conditions otherwise favor it.

In the absence, then, of evidence to the contrary, it is fair to concede that in this case infection occurred during a prolonged, intimate contact with one or two presumably careless consumptives, and that a tuberculous lesion became manifest immediately at the close of this period of exposure.

(*b*) The earliest clinical manifestation of disease then was undoubtedly the attack of pleuritis with effusion, notwithstanding opinions to the contrary at the time of the attack and immediately afterward. And this brings us to the point of chief interest to the present discussion.

(*c*) The phenomena attending the first arrest of the disease. The attack was sudden and sharp—in fact, a typical, tuberculous pleuritis, and there followed the usual prompt and complete convalescence which so frequently lulls suspicion and encourages relaxation of after vigilance; indeed, even when recognized as tuberculous, this form of onset, by pleuritis with effusion, has, I think, come to be regarded clinically as most promising in prognosis. There seems to follow these sharp pleuritic invasions a more rapid and vigorous immunizing process in the organism, and I should say, though I cannot at the moment substantiate my opinion, that there are fewer relapses among patients of this class than is the case where the onset is characterized by intrapulmonary changes. After the absorption of the fluid, physical signs in the chest disappeared, together with all other symptoms; the return to normal was so complete in fact that every assurance was given to the patient, and family that the attack was not tuberculous, but with the knowledge of its true nature, which subsequent events made possible, one can see in this convalescence all of the clinical features, in miniature, as it were, which characterize the healing of tuberculosis; this arrest of the disease, moreover, was, perhaps, as I ventured to say with regard to the other case, as complete as is ever possible in this disease.

The chief causative factor in the recrudescence which occurred in this case was obviously the exposure to unhygienic habits and environment, and there is no sufficient reason to believe that such recrudescence would not have followed similar exposure, even if suitable precaution on the part of the patient had prolonged the interval of arrest to five years, *i.e.* the period generally conceded as justifying the term cured.

It is rather curious I think, and worthy of note, that in this case the infection took place while the patient was living in the open air and under fairly ideal climatological conditions, that arrest of the disease, followed by subsequent periods of apparent perfect health, occurred in a climate supposedly very conducive to the development of tuberculosis, and finally that recrudescence occurred in a climate and at an altitude world-famed for its curative virtues in this disease. Of course, there is a sufficient explanation in each instance, but it all goes to prove that care is a more important element than climate in effecting the development, as well as the cure, of tuberculosis.

Before turning from a subject, which, though necessarily interesting, is, I fear, an unpardonable digression, I wish again to call attention to the frequency with which it is possible to trace in the history of a tuberculous patient a first presumptive evidence of disease, followed by a more or less extended interval of apparent health before arriving at the demonstrable onset, which, in the light of the history, must be considered a recrudescence. Thus, in the last thirteen cases discharged "apparently cured" or "arrested" from the sanatorium, whose physical condition upon admission (irrespective of the history) justified a classification as "early with mild symptoms," *i.e.* incipient, the average time elapsing since the first presumable evidence of disease was found

to be one year and ten months, with a maximum of six years and a minimum of four months. On the other hand, the early acute cases seldom give a history of more than a few months from the first presumptive evidence.

This seems to lend support to the view that the first development of tuberculosis is characterized by more constitutional disturbance than is generally imagined. It is probable that a very large proportion of the "grippes," "malarias," "typhoid fevers," etc., which find their way into our history charts represent in reality the acute constitutional manifestations of the early stages of the disease. Furthermore, it seems not unlikely that these early acute symptoms may be the result of definite reactions essential to the immunizing process in the organism.

To consider more specifically the various clinical features of a healing tuberculous lesion, it is desirable to assume a more or less typical clinical picture of the disease—one which shall present well-marked physical signs in the chest and the classical symptom complex. Assuming that such a case be brought under conditions favoring recovery, and that convalescence supervenes, the first and most important clinical evidence of the onset of the disease, the fever, will also be the first and most important symptom to disappear. Arrest of activity in a tuberculous focus can never be said to have been accomplished until there has been an absolute return to normal of the temperature, and a relative approach to normal of the pulse rate and arterial tension.

The disappearance of fever in such cases is a feature which suggests that a degree of immunity has been established without which the healing process cannot go on. With the subsidence of fever there follows an improvement in appetite and digestion, as a rule, and correspondingly an increase in weight. These features are especially marked in the convalescence which follows the first outbreak of the disease, and remind one of similar phenomena which occur after typhoid. An improvement in the general health and vigor of the patient follows, and altogether the rebound frequently carries the patient into a much better physical condition to all appearances than was the case prior to the attack. Unless, indeed, the tuberculous nature of the attack has been demonstrated beyond a doubt, the prompt and apparently complete return to health is often liable to be interpreted as an evidence that the attack was non-tuberculous, and subsequent precautions against relapse neglected in consequence.

In the arrest which follows a first onset of the disease physical signs in the chest disappear with comparative celerity, together with the fever and disturbances of nutrition. With the cause thus removed, cough and, if there be any, expectoration cease, and there is left in a surprisingly short time scarcely a demonstrable evidence of any departure from normal. With every subsequent recrudescence, however, as would naturally be expected, structural changes in the lung become more extensive, and the repartive process is correspondingly retarded. The fever may subside almost or quite as promptly as before, and the weight, if decreased, may be regained, while cough and expectoration and physical signs in the chest persist with a tenacity often discouraging to both patient and physician. Finally, when several relapses have occurred, or when healing has been for any reason much delayed in the case of a first outbreak, organic changes become permanent, and certain physical signs, which may be said to be indicative of a healed lesion, remain never wholly to disappear.

In the acute stage of the onset or recrudescence of a tuberculous lesion, as in most other toxæmias or septic infections of an acute nature, there appear abnormalities in the urine, both in chemical reaction and in the character of the formed elements, though unfortunately these are not sufficiently distinctive with our present knowledge to be pathognomonic. They consist chiefly in a more or less transient and intermittent albuminuria and the presence of hyaline casts and cylindroids, together with epithelium, leucocytes, and not infrequently red corpuscles in the sediment. Apparently these signs do not signify more than a temporary renal congestion, since they readily disappear early in the healing process. Even a transitory diazo-reaction may be present during the first acute onset without unfavorable prognostic significance.

Dr. Neagle, of my staff, has recently summarized and tabulated from the sanatorium records the clinical features of fifty discharged cases. He has divided these into groups, according to condition on admission, as follows:

(*a*) Fourteen early cases, with slight pulmonary involvement.

(*b*) Twenty-five cases, presenting moderate constitutional disturbances, but more or less extensive pulmonary involvement, and an average presumable duration of disease of five years, including intervals of arrest.

(*c*) Eleven cases with acute or otherwise unfavorable manifestations, either local or constitutional, and with a presumable average duration of disease of two years and two months.

Some of the results of his investigation have an interest in the present discussion. In Group *a*, for instance, he found that upon admission, or at some time during sanatorium residence, there was present a positive diazo-reaction in two patients, both of whom were discharged "arrested," and are still apparently well.

In Group *b* diazo-reaction was positive some time during observation in four patients, one of whom died, and three were improved and are still living, the reaction disappearing before discharge.

In Group *c* (the unfavorable class), on the other hand, diazo-reaction was positive in seven patients, five of whom died in residence, and the other two were discharged unimproved, and are probably now dead.

It would seem that the generally accepted prognostic significance of a diazo-reaction in tuberculosis has application chiefly, if not solely, to the last stages of the disease, and when temporarily present in the early acute manifestations, or in acute exacerbations of chronic lesions, need not necessarily indicate an unfavorable termination. It is unnecessary to add that its disappearance, if present, would be one of the first clinical evidences of improvement.

It seems probable that the work which has been, and is being, done on the blood will in the end throw valuable and, perhaps, unexpected light upon some of the most obscure clinical problems of to-day, and especially, I think, is this line of research promising in tuberculosis. If we are ever to be able to recognize the presence of tubercle during the period of arrest following first and unrecognized onset, it would seem to me that we are most likely to do so through discovery of definite reactions in the blood serum of the infected. Already much preliminary work has been accomplished, and, although it is not as yet of practical clinical value, there is no reason to believe that it will not become so. The great expectations from this line of research, which the results already accomplished certainly justify, should be sufficient to secure more than the necessary moral and financial support to such invaluable institutions of research as the Saranac Lake Laboratory. The

discovery of a means of diagnosis, more accurate, if not more safe, than is tuberculin in suspected persons who are supposedly non-tuberculous, would be as great a boon to humanity as that of a curative serum.

From the crude and more superficial methods of blood study now practically available to the clinician not much of importance is to be learned. As a rule, in the healing process there is a moderate anæmia and a slightly more pronounced chlorosis to be overcome, and the reparative process in the blood follows closely the reduction of fever and improvement in nutrition. In early and uncomplicated lesions without softening, there is, of course, no leucocytosis, but much earlier in the disease than is I think generally imagined there appears an increase in the white cells. This is not necessarily much, if any, above the limit which normal blood may reach occasionally during the day, but it is constant until arrest of activity is achieved.

In twenty-five cases discharged from the Sanatorium, apparently cured or with disease arrested, and who represented upon admission various stages of the disease, with a mean duration since the presumable onset of two years, three and one-half months, observations on the blood were recorded showing the following averages:

	Erythrocytes.	Leucocytes.	Hæmoglobin.	Color Index.
On admission	4,890,000	10,760	86%	.879
On discharge	4,950,000	9,360	92%	.929

In these cases there was an average gain in weight while under observation of 14 pounds 8 ounces. In every case reaching to or passing the previous greatest known weight there was a return to normal of temperature and pulse, but cough, expectoration, and bacilli were present upon discharge in some of them. In Dr. Neagle's Group *a* the averages were somewhat more characteristic. It will be remembered that this group was made up of fourteen early cases with slight local and constitutional disturbance (these cases were not all, of course, successfully arrested). The following table shows comparison of the average blood values upon admission and discharge:

	Erythrocytes.	Leucocytes.	Hæmoglobin,	Color Index.
On admission	4,950,000	9,850	87%	.878
On discharge	5,080,000	8,310	93%	.92

It must be borne in mind that these examinations were made at an altitude of something over 2,000 feet, which explains the rather high counts of both red and white cells, as compared with what is usually observed at sea-level in similar cases.

It appears unnecessary to dwell longer upon clinical details, which are familiar to every one who has had an opportunity of observing the progress of a healing tuberculous lesion. In a subject which has been so voluminously treated it is very difficult to offer suggestions for further clinical study which can have the least merit of novelty. Nevertheless, I venture to emphasize, in conclusion, one or two features which it seems to me are at least worthy of investigation. Let me state them as propositions:

(1) It is probable that the initial lesion following a tuberculous infection is often obscure in its clinical manifestations and frequently escapes identification.

(2) There is nearly always a prompt and very often successful tendency on the part of the organism to a more or less complete repair followed by an interval of apparent health.

(3) Following this interval, which may extend into a period of years, there is a strong tendency to relapse.

(4) What is in reality a recrudescence of an arrested lesion is very frequently mistaken for an initial onset.

(5) Whatever may be the facts in an individual case, the safest and most practical policy lies in regarding every apparent recovery from tuberculosis as merely an arrest of the disease, brought about by an acquired immunity which suitable conditions are very prone to destroy.

THE ART OF EATING PROPERLY (EUPHAGIA) AND THE HARM OF EATING TOO RAPIDLY AND TOO SLOWLY (TACHYPHAGIA AND BRADYPHAGIA).

By MAX EINHORN, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE N. Y. POSTGRADUATE MEDICAL SCHOOL.

EATING or partaking of food is our principal means of sustaining life. Without this the organism cannot thrive, cannot gain in weight (grow), and can exist only a short while. During the time of total abstinence the body lives from its own substance, steadily losing in weight, and soon dies. It will therefore not be out of place to devote our attention to this subject.

In the animal kingdom as well as also among uncivilized peoples, the obtaining and taking of food forms the principal occupation during life. The necessity of obtaining food has remained the same with civilized man, but the manner of partaking of it has been changed partially to his disadvantage. New interests have arisen and the act of eating has been partially relegated to the background. Many busy persons scarcely take time to eat; they swallow hastily any kind of food without special selection, at times poorly prepared. The natural consequence of this is that under these conditions diseases of the digestive system develop quite frequently.

I may be permitted to describe first in a few words the art of eating properly (euphagia) and then discuss two improper modes of eating (tachyphagia and bradyphagia).

Euphagia.—Like all natural processes, the partaking of food, if done in a correct manner, affords the body pleasure and satisfaction. For this purpose, however, the organism must be prepared by previous work and subsequent rest. Already in the Bible the following quotation is found: "In the sweat of thy brow shalt thou eat bread." This shows the importance of work on eating. A similar proverb exists in the German language: "Arbeit macht das Leben süss" (Work sweetens life), which sentence naturally refers not only to eating but to all functions of life. Granted, however, that work is necessary, yet it must not be in excess or lead to exhaustion, as in this condition the appetite usually disappears and digestion becomes sluggish.

Meals are best taken during those periods when the body is at rest. The time for taking food must not be too short. During the meal it is better not to think of business, or serious, or, perhaps, even sad things. Our whole and undivided attention should be given to our meals. Pleasant company, light conversation, jokes, and stories add to the enjoyment of food.

It is generally known what a powerful influence the brain exerts over our digestive faculties. Great grief robs us of our appetite and may cause real disturbances of digestion. Pawlow has lately established the physiological importance of the mental state on digestion, having shown, for instance, that delicacies produce secretion of gastric juice as soon

as they are perceived by the eye, even before they are eaten.

The food must not only be palatable, but must be served in an attractive manner (fine dishes, table decorations, etc.).

In eating we must take time to chew our food thoroughly. This serves a double purpose: (1) through the act of mastication the coarser particles of food are broken up; (2) more saliva is secreted and is thoroughly mixed with the food. The digestion of starch is thus materially aided, and the proteids are made more easily accessible to the action of the gastric juice.

Water should accompany each meal. It increases the appetite and the enjoyment of food. It also serves a useful purpose when substances are taken into the mouth, or even swallowed too hot. A mouthful of cold water will at once lower the temperature and obviate any danger of burning.

After eating we should rest a little while before returning to our work.

Tachyphagia, or hasty eating, is a common evil. The food is only half masticated, or not at all, and enters the stomach without being properly insalivated and comminuted. It is easily seen that thus the foundation for many a stomach or bowel ailment is laid. The coarse food causes too much irritation to the gastric mucous membrane, and it is not sufficiently acted upon by the gastric juice, which usually only affects the external surface, leaving the rest unchanged. This refers particularly to the digestion of albuminoids. Starch, however, under these conditions is also left without any alteration, because the ptyalin of the saliva is not present in sufficient quantity. The chyme, therefore, reaches the bowel practically unchanged, causing here almost a state of irritation. Besides the mechanical effect, however, tachyphagia has other drawbacks, because it encourages the taking of large quantities of food in too short a time, and the consumption of foods too hot or too cold. In eating correctly a provision is made that not too much food passes into the stomach at once, for mastication requires time; besides there is some time spent in conversation and in serving the different courses. The temperature of food and drink is partially equalized by the slow passage through the mouth and œsophagus. All these factors are absent in eating too rapidly, and we thus have the two obnoxious points spoken of above, viz., unsuitable quantity of food and unsuitable temperature—two conditions that often cause digestive disturbances.

Clinically the disadvantages of tachyphagia are so well known that it does not seem necessary to illustrate them by means of examples. Every physician has observed cases of gastric and intestinal catarrh, hyperchlorhydria, and other tedious digestive disturbances, the etiological factors of which could be found in the existing tachyphagia.

Bradyphagia.—By bradyphagia (eating too slowly) we understand a condition in which the eating is performed abnormally slowly, so that the body economy is thereby injured.

In general we as physicians, will more often have to battle against the above described tachyphagia, advocating a properly slow, or, more correctly, a rational mode of eating. This, however, may be, and is indeed overdone by some persons to their detriment. In such cases every morsel is masticated and remasticated, and before being swallowed is again chewed and everything carefully tested with the tongue, whether it has been thoroughly comminuted. An abnormal fear and suspicion develops in this manner, and for such a person eating is a difficult task. The enjoyment and pleasure of eating are transformed into a doleful process, and thus frequently a smaller quantity of food is taken than usual. Not rarely it happens that the bolus occasionally remains in the pharynx or œsophagus and refuses to budge. It is not an organic affection that causes this variety of dysphagia, but merely the excitement and fear of eating. In these cases, in course of time a chronic inanition develops owing to bradyphagia and the added temporary dysphagia, in consequence of which the patient gradually becomes weaker and occasionally dies, unless we combat the evil energetically at once.

Since bradyphagia is a comparatively rare occurrence, I do not hesitate to give a few examples of it.

Case I.—April 2, 1896. G. I. L., 32 years old, lawyer, has suffered for the last five or six years from digestive disturbances. He has lost considerable flesh, and has been unable for the last three years to attend to business. He complains of his inability to swallow food and of intense pains in the upper abdominal region, particularly after meals. He has lost in all about 40 pounds, of which the smallest quantity in proportion was lost during the last six months. He keeps to a strict diet and eats very slowly, taking a half hour to consume a glass of milk.

Status præsens. The whole body is emaciated; examination of the thoracic organs gives negative results; the stomach extends to about two fingers' width below the navel. The epigastrium is slightly sensitive to pressure. One hour after test breakfast the stomach contents showed the presence of free HCl, and an acidity of 78. The swallowing sound occurred seven seconds after the drinking of water.

In the absence of any organic lesion the diagnosis of neurasthenia and hyperchlorhydria was made. The difficulty in eating was explained by the psychic excitement subsequent to the sitophobia and bradyphagia. The patient was put upon a more liberal diet and advised to eat more quickly. In three weeks he gained eleven pounds; he continued to gain in weight and recovered entirely.

Case II.—March 23, 1903. Mrs. R. F., about 35 years old, has been suffering from digestive disturbances for the last three years. She claims to have pains in the epigastrium after every meal, and suffers much from belching, constipation, and lack of sleep. She is much run down and has been unable for the last two years to look after her household duties. She says that she eats only the lightest foods (principally liquid diet) with the greatest care, requiring twenty minutes for the ingestion of half a plate of soup, and twenty-five minutes for a cup of milk. Owing to these important precautions, she is obliged to take her meals alone. She is surprised that in spite of all this she does not improve. The diagnosis of neurasthenia, hyperæsthesia of the stomach, and bradyphagia was made. The patient was told to eat a variety of plain and simple foods, and to eat and drink more rapidly. In two or three months she had completely recovered. She ate with the rest of the family and was again able to attend to her household duties.

Treatment of Faulty Eating. (Tachyphagia and Bradyphagia).—All persons who eat too fast should be warned by their physicians. They should be told to take more time for their meals and to chew their food thoroughly. If the time for eating is occasionally too short, as in railroad journeys, etc., it is better to omit the meal or to take only something fluid (a glass of milk, a raw egg, or some beef tea).

To combat bradyphagia—observed in neurasthenics, and only rarely even in them—we must take active measures, as it is impossible to cure them as

long as the bradyphagia exists, owing to the too small quantity of food ingested. They should be told to eat more and more rapidly, and not to take too small bites or to chew too long. Fluids must be taken in larger quantities (not teaspoonfuls at a time). They should not take their meals separate from the rest of the family, but should eat at the common table and finish at the same time as the others.

Frequently these instructions alone will be sufficient to correct this fault. If, however, this is not the case, then we must take refuge for a time in sedative drugs (bromides, valerian, etc.), in order to allay the psychic excitement during the time of eating. If the patient, with the aid of these drugs, has accustomed himself to take a few meals in a correct manner without suffering, he will then usually have enough confidence in himself with regard to his ability and will get along without medicines. The removal of bradyphagia will frequently smooth the path to convalescence and enable the patient to get entirely well.

A RECENT EPIDEMIC OF TYPHOID FEVER.

By JOHN BRADFORD BRIGGS, M.D.,
WASHINGTON, D. C.

On March 18, 1904, I was asked by the head of a small community on the Alleghany watershed to act as resident physician during the course of an epidemic of typhoid fever which had just become locally prevalent. The origin and spread of the disease, under conditions which made their exact study very satisfactory, offered so many points of interest that it has seemed wise to report the facts as they came under observation, as a small contribution to epidemiology. In another place* attention has been called to some clinical features of unusual interest that characterized the outbreak, and the present paper will deal with bedside peculiarities of the infection only so far as they seem of value in connection with the study of the spread of the fever.

The community in question is composed of some 600 souls, dwelling or having their daily occupation among buildings situated on the top of a small plateau which is bounded on each side by a deep valley, or ravine. The southern ravine contains some dwelling houses, and is also overlooked by a row of houses occupied by small families. In the center and about the sides of the plateau are the main buildings, housing one-third or more of the inhabitants, the rest of whom live in adjoining towns, spending only the day on the higher ground. Of those living above, the majority are minors—there are many young adults and few aged persons, the general personnel being of the type and age most susceptible to typhoid infection.

The plateau which is the site of the main building runs back into a rolling hinterland, being separated from contiguous heights by the deep and narrow valleys of erosion on either side, this depression being longer and extending farther back on the southern aspect. The underlying rock formation is metamorphic, the principal industry of the neighboring town being the quarrying of granite, and numerous cracks and fissures produce a quantity of surface springs, water appearing at many points throughout both valleys, especially near the head of the southern one. There are two sources of supply for water, or were at the time when typhoid fever broke out,—one a new reservoir about a mile from the central buildings, drawing its water from excellent deep springs, and the other a surface spring just back of these buildings, at the head of the southern valley. Water from both sources was delivered to the Inn, where all those residents who did not have separate houses took their meals. When spring water is mentioned in what follows, reference is made to this one spring whose water was used. This spring comes to the surface on the side of the southern declivity at the head of the ravine, only a few feet below the local infirmary, on the same watershed with which it is situated. Surface drainage from the neighborhood of this infirmary, and from that of dwellings located on the opposite side of the ravine, would tend to mix with the waters of this spring, both directly and by draining into its sources in the rocky hillside.

On January 26, 1904, a young man who had spent Christmas in Pittsburg, where there were at the time many cases of the disease, was admitted to the infirmary suffering from typhoid fever. His case ran the usual course, ending in recovery, and on March 4 he was discharged from further treatment, returning at once to his home. During the six weeks of his illness the weather was very bad, there being some heavy snow and rainfall, and the ground, which had been frozen during the coldest weather, repeatedly thawed out and became soft and boggy. There was a tremendous amount of surface drainage throughout most of this period, and the culverts through which this water was conducted overflowed on at least one occasion. Every climatic condition was present which would favor the dissemination of infectious material through the superficial springs, if any such material had been present during this period in or upon the higher ground. In the month of February a young woman living on the hill, and drinking the water of the Inn, was in all probability suffering from the prodromal symptoms of typhoid fever; but the winter had been a hard one, there had been many cases of catarrhal affections of different kinds, and no suspicion was entertained that the local water supply had become infected until the first part of March. In the first week of that month a woman who was living at the Inn became ill, and her case was immediately recognized as one of typhoid fever. Still, it was not until ten days later, when half a dozen cases broke out simultaneously, that it became evident that the disease had obtained a firm foothold, and promised to assume epidemic proportions. A majority of the members of the community, possibly 500 in number, went away at once or within the next ten days, leaving behind only the sick and their families, the persons in authority, and the necessary staff of servants and employes. Local conditions made this exodus necessary, though it was appreciated that the scattering of possibly infected persons about the country might favor the further dissemination of the disease. Every advice and warning was given to assure the careful observation of these persons by their home physicians during the possible period of incubation, so that no new case at a distance could serve while unrecognized as the focus of importation for a new epidemic. Among those who went away, 27 proved to have been infected before they left, and developed typhoid fever within the incubation period, one of the patients dying after a long journey by rail. Of those who remained, including the original cases, 18 altogether were affected by the fever. Of these latter, two individuals undoubtedly contracted their infection through direct or indirect contact with one of the original cases.

The personnel of the community could be roughly

*"The Mild and Abortive Forms of Typhoid Fever" *American Medicine*, Oct. 8, 1904.

divided, so far as concerned the conditions of their possible exposure to infection, into the following classes: (*a*) Adults and minors living in the main buildings, (*b*) adults and minors living at a distance, spending only the day on the hill, and eating a daily or occasional meal at the Inn, (*c*) families living in certain separate residences on the hill, and (*d*) families living in the southern valley or on its southern slope. Those belonging to class (*b*) practically all left after the explosive outbreak, and almost all of the younger people of every class, except those already sick, went away when the alarm was taken, or ceased their daily visits. Cases of typhoid fever occurred among all of these groups except the fourth, whose houses were supplied with water derived from an entirely separate watershed.

At the time of my arrival there was only one of the permanently resident adults down, but soon afterwards two cases developed among those who were still in residence, and one case among those who had left; so that it became evident that the common source of infection was to be sought in some condition that was capable of affecting all of the first three groups indiscriminately. The milk supply was not long under suspicion, as none of the local dealers was bringing milk to all of the houses in which the disease had manifested itself. No other possible point of origin for the epidemic suggested itself as probable except the drinking water, to which pointed in itself the explosive character of the outbreak, and all attention was accordingly directed to the reservoir and the tributary spring. Samples from both these sources were taken and submitted to bacteriological examination, while the distribution of the cases on the grounds was looked into with some care, in the hope of obtaining some accessory evidence of value. As it happened, the facts furnished by this inquiry were in themselves practically adequate to the solution of the problem, had the bacteriological laboratory not been accessible.

Considerable local prejudice existed against the water obtained from the new reservoir,—it contained a large number of a minute alga, *Uroglæna* (?), and was brownish and turbid, besides developing a nauseous odor when heated, the hot water from the pipes being less than agreeable for bathing purposes. The spring water, on the other hand, was clear and of an agreeable quality for drinking, having no suggestion for sight or taste of anything unhealthful. On March 20 the pipes had been emptied, while the residents were ordered to use none but boiled reservoir water for any purpose. These instructions were probably carried out to the letter.

It was found that the people on the hill, with the exception of those belonging to group *c*, who occupied a separate row of residences overlooking the southern ravine, had been drinking habitually the mixture of the water from the reservoir and spring, as it was delivered to the Inn. These separate dwellings are new, and have a common water supply, derived from the reservoir alone, without any admixture from the spring. It was this fact that furnished the clew we were seeking. In these houses, sheltering altogether about 45 individuals, including servants, there were no cases of typhoid, nor did any occur subsequently, except in the house of Mr. F. Here, out of six inmates, four came down with the fever, including two guests who had been visiting during the month preceding the outbreak. On inquiry it developed that the F. family had been in the habit of using the spring water, unboiled, and had so used it, on account of its pleasant taste for drinking purposes, up to a time well within the period of incubation required for all of these cases.

In the meantime the bacteriological report made by Dr. Ford, of the Johns Hopkins Hospital, gave a clean bill of health to all the sources from which samples of water had been taken, and though we were convinced that the infection arose from contamination of the water supply, it was feared that it might be impossible to discover the origin of this contamination, and that the conditions underlying the situation had been of a purely temporary nature and might now be indeterminable. We felt, however, that the evidence afforded by the occurrence of the disease in the F. house, with the complete immunity enjoyed by adjacent families using reservoir water continuously, was not a mere coincidence, and that if it should eventually prove impossible to obtain any confirmatory bacteriological data, still the clinical facts were sufficient to condemn the spring as the probable cause of trouble. This feeling was accentuated by the history of the first case, which was in the infirmary from January 26 to March 4. The bowels of this patient had been very constipated, the stools hard and scybalous, and disinfection had been attempted by means of corrosive sublimate solutions. The action of bichloride of mercury in coagulating the proteids of the stools, and the particularly hard consistency of the dejections in this case, made it seem at least probable that disinfection by this method had been inadequate, and that active typhoid bacilli had been passing down the sewer pipes leading from the infirmary during the whole period in which they had been cast off from the patient's intestine. Assuming that a leak had existed in this pipe system anywhere above the level of the spring, whose situation has been described above, it would have been impossible for any matter escaping through such a leak not to flow almost directly into the spring, through but a few feet of soil as an intervening filter. The ground is very rocky at this point, and fluid material would be subject to but little filtration from the overlying earth.

Fresh samples of water were taken from the spring, both by Dr. Ford and by the bacteriologist of the Board of Health. It would have been very desirable to have secured water from the spring at a much earlier time, when the contamination, now evidently not considerable, had been at its worst. It was found possible to obtain some water which had been standing at a bend in the supply pipe and had not been run off when it was emptied, and which had probably left the spring as early as the middle of February. From this water, and on this occasion from that of the spring itself, both Dr. Ford and the State bacteriologist were able to isolate an intestinal organism pronounced by Dr. Ford to be an unmistakable variety of the human colon bacillus, and a necessary bacteriological proof of sewage contamination of the spring water had been furnished. The situation of this spring, and the fact that it was covered with an iron plate, made it seem incredible that the influx of fecal matter had taken place in any other manner than by seepage through the soil. It had at one time been considered as a remote possibility that a direct accidental soiling of the spring might have occurred through the urine of the first case, while convalescent; but apart from the unlikelihood of such an act, and from a careful inquiry into this patient's habits during that period having failed in any way to confirm this possibility, the finding of the colon bacillus left no hypothesis open but that of contamination with fecal material.

The sewer of the infirmary passed in its course

to its final outlet in a distant stream, within about one hundred feet of the covered spring. No point of leakage in the pipe could be found anywhere in the vicinity of, or above the spring, and it was evident from the bacteriologist's findings that any leak that presumably had existed was at the time of our investigation not open, or at least was not allowing the escape of sewage in any considerable amounts. The suggestion was made of choking the sewer at some lower point, and so artificially producing a condition of heightened hydraulic pressure within the drainage system, to determine if in this way sewage could be forced from it into the spring; but it was decided to wait until later, and then to uncover the whole length of the pipe between the infirmary and the spring, with the idea of getting directly at the seat of trouble. It would be vastly interesting to know the results of such an investigation. Just below the infirmary is a manhole leading into an elliptical brick-walled vault, some four or five feet deep and of about the same larger diameter; through this vault passes all the kitchen and closet drainage from the infirmary. During the months of March and April, while our investigation was in progress, the floor even of this vault was never entirely covered, even when the closets were simultaneously flushed, and all the water taps turned on above it; but there was visible on the wall of the vault, at a height of some two and a half feet above the floor, a stain which evidently marked the height to which sewage had reached, at some time in the few weeks previous. That at the time when this high level was attained, probably during the period of thaw and freshet that occurred in January and February, sewage was forced out, either through a crack in the wall of the vault or at some lower point, the defect being in all likelihood a small one and one which was covered only at a high state of the water—seems as certain as anything can be which rests on circumstantial evidence alone.

The further course of the outbreak confirmed our conclusions. The interdict on the use of the reservoir water was removed, the spring was closed and made inaccessible, and the community returned to the use of raw milk according to their usual habits. Of the new cases arising after the spring water was cut off, all were among those who had been accustomed to use this water, and in all the invasion occurred within the period of incubation, as calculated from the date when spring water ceased to be supplied to the Inn. This statement neglects two cases, both arising considerably later than would be probable if their only exposure had been through infected water; both of these cases, one of which was in a nurse, undoubtedly arose by infection through immediate contact with patients, and had nothing to do with the condition of the water supply.

The conditions of this outbreak, as set forth above, teach no lesson that is new, but they serve to give an additional and very vital emphasis to long-recognized principles, which do not always receive the respect which is due them. Of these, the two most important concern the choice of the sources of drinking water in small communities, and the very essential matter of the proper use of disinfectants in the effectual prevention of the spread of typhoid fever. Palatable water is not always pure, and that containing an unpleasant looking or offensive smelling sediment is not necessarily polluted with sewage. The choice of a source of supply should be determined not only by the quality of the water at the time of its examination, no matter how pure it may be shown to be on analysis, but by the location of the source as well, and the opportunities that *might* occur for its contamination, under the usual conditions of community life. It may be safely stated as an absolute rule that no surface spring should be used to supply drinking water, which is situated below a dwelling-house in such a position that excrementitious matter could be carried from the neighborhood of the house to the spring by natural agencies, under even the most unusual conditions of storm and weather. Still more to be condemned is the laying of sewer pipes in proximity to a source of water supply. When the dwelling shelters patients suffering from a communicable disease, and the sewer, no matter how perfect its construction in the opinion of sanitary engineers, drains such a house, the use of water from the source in question is nothing short of foolhardy. Esthetically it is abhorrent, and its recommendation by any authority carrying a dangerous conviction is as criminal morally as it is negligent professionally.

And yet the main point to be noted concerns the problems not of engineering, but of purely medical prophylaxis. There is nothing more worthy of thoughtful attention than the absolute certainty with which we, as physicians, can control the dissemination of the bacillus typhosus, provided that we recognize with certainty the disease which it produces, and provided that we know how to isolate patients suffering from it, once it is recognized. The isolation of a case of typhoid fever so that it will not be a source of danger to other people is such a comparatively simple matter, and one that is so little liable to injure the susceptibilities of the patient or his family, that it would appear to be of all prophylactic measures one of the most easily carried out. Cole's* conclusions, summing up all the experience of the last few years in this field, are brief and easy to remember. The lime preparations, formaldehyde, etc., are not safe or efficient in the disinfection of stools and urine, except when very carefully controlled. They may be, in the individual case, perfectly safe and absolutely to be relied upon, but under unfavorable circumstances they are worse than useless. Solutions of bichloride of mercury may be safely used to render the urine harmless, but they are never to be relied upon in the case of stools. The bichloride after a time hinders its own germicidal action, and even in the case of a fluid stool, covers any formed particles with an impenetrable coating of albuminate, which effectually protects the bacteria deeper in the center of the fecal mass. With scybala, the disinfecting power of bichloride is almost nil. The only method of disinfection of typhoid stools which is beyond criticism, besides cremating them or boiling them in antiseptic solutions, is by the use of carbolic acid in the strongest possible solutions. Carbolic is cheap, and on that account may conveniently be used in excess; it does not coagulate the proteids of the stools, but on the contrary penetrates deeply after continued exposure. It should be used in 5 per cent. solution, in volumes exceeding by two or three times that of the stool, and it should be left in contact with the fecal matter, after very thorough admixture, for at least two hours, three hours being advisable. Carbolic acid may also be used with advantage in the disinfection of the urine, every ounce of which should be sterilized before it is thrown out, whether manifest bacteriuria is present or not. For soiled linen, boiling, or else immersion for two hours in carbolic solution, is as necessary as is the care of the dejections. The bath water, also, should always

*The Prevention of Typhoid Fever, *Journal of the American Medical Association*, May 28, 1904

be regarded as capable of disseminating the virus of the disease, and should be disinfected before being thrown away, the purpose being satisfactorily accomplished by allowing it to stand for an hour after the addition to it of fresh chloride of lime, a quarter of a pound being sufficient for the contents of the ordinary tub.

Whether the sewerage of the locality where we see our patients is surely and absolutely separated from the water supply or not, the manifest duty of the physician in attendance upon every case is to make perfectly certain that not one particle of infectious material from his patient enters the drain pipes without first being rendered harmless. Only in this way is typhoid fever ever to be controlled in this country, and only when efficient precautions are taken in every case will this disease cease to be "the scourge of autumn."

THREE CASES OF EXCESSIVE FETAL DEVELOPMENT.*

By JULIUS ROSENBERG, M.D.,

NEW YORK.

LECTURER ON OBSTETRICS, NEW YORK POLYCLINIC MEDICAL SCHOOL

If a fetus weighs ten pounds or more its weight and size are excessive and delivery will be difficult and complicated. Oversize and advanced age of the parents, also multiparity and pregnancy protracted beyond the normal terminus, are said to predispose to excessive development; and this is apparently borne out by my observations. Children having such abnormal dimensions are too large for the normal pelvis and cause complications similar to those met with in pelvic contractions. It is a most difficult condition to diagnose, and as a rule is not discovered until labor has been prolonged and attempts to deliver have proved futile. The opportune time for successful cesarean section has then passed, and the mothers are served best by perforating the dead or moribund child.

This appears to be the opinion of most writers, and the rule is a good one never to overcome bony resistance by protracted forceps traction, but rather diminish the size of the child through embryotomy.

Case I.—A normal pelvis and a normal position of the fetus generally indicate in the absence of other abnormal conditions a normal labor and puerperium. In this case the woman had a normal pelvis and the fetus was in L. O. A. position; the case, nevertheless, was one of the most difficult I ever attended, and in which every obstetrical operation, symphyseotomy and cæsarean section excepted, was performed.

Dr. W. requested me to see with him Mrs. O., I-para, 36 years old. The doctor stated that the woman had been in labor almost 24 hours, and because labor did not progress he had ruptured the membranes six hours before my arrival. I found a large fleshy woman, weighing little short of 200 pounds. The external pelvis measurements were: Spin. ant. sup., 25 cm., crist. il., 27 cm., trochanters, 31 cm., conjug. ext., 19 cm. The abdomen was large and distended, but not sensitive. The uterus contained one fetus with the head movable above the brim. Heart sounds to the left of the umbilicus and normal. The promontorium could be reached with difficulty and I estimated the true conjugate diameter to be about 11 cm. The os barely admitted two fingers. The head, as mentioned before, was movable and not engaged. Pulse and temperature normal. Labor pains not very strong, about every five minutes. In the absence of urgent symptoms I advised to wait. Forceps and version were impractical and the mother's and child's condition did not justify cæsarean section or craniotomy.

After 24 hours I again saw the patient without finding much change in the patient's condition. Os the size of a silver dollar, head still above the pelvic brim, temperature normal, pulse slightly accelerated, stomach irritable. Fetal heart-sounds normal. While fully appreciating the desirability of terminating labor, the conditions were such that further delay was advisable. It should be remembered that the membranes had been ruptured thirty hours before, and all liquor amnii having drained away version was difficult if not impossible. The undilated cervix with the head above the brim certainly contraindicated the application of the forceps. The living fetus in the absence of urgent indications, excluded craniotomy, and the normal pelvis diameters ruled against symphyseotomy and cæsarean section. Thus I was forced to advise further delay, hoping that under the influence of stronger pains, the head would mould and enter the pelvis. I agreed, however, to apply the forceps should there be no progress after a further lapse of twelve hours.

Twelve hours later, the conditions concerning the advance of labor remained unchanged, but the patient showed unmistakable symptoms of exhaustion. I therefore decided to apply the forceps to bring the head into and through the pelvis. The cervix was dilated until it admitted my whole hand, after which I applied the forceps. In spite of vigorous traction the head did not advance, and after satisfying myself that the forceps would not accomplish delivery I removed the instruments. I also realized that symphyseotomy would offer no advantage, the disproportion between head and pelvis being apparently more than three-quarters of an inch, the space gained from a division of the pubic joint. Cesarean section gives most disastrous results after protracted labor. I therefore advised, although the fetus was alive, immediate craniotomy, which however was refused for religious reasons. I waited until the heart-sounds had become inaudible, and then perforated with Naegele's perforator, removing the cranial contents through irrigation. The cranioclast brought the head down and into the pelvis, but the shoulders, in spite of strong traction, did not follow. Seeing that delivery of the body could not be accomplished in the usual manner, I applied the blunt hook in the axilla, but the shoulders did not descend although I now made traction with both hook and cranioclast. As the head was only an obstruction I decapitated, brought down an arm to be used as a tractor, but even this diminished diameter proved too large for the pelvis. I next performed version, a most difficult procedure, but only after eventration and removal of the thoracic contents, could I deliver the fetus. The fetus minus brain and blood weighed fourteen pounds. The woman sustained a vesicovaginal fistula subsequently repaired, otherwise she made a good recovery.

In reviewing this case, the first question to be answered concerns the loss of the child, whether or not its life could or should have been saved. There is absolutely no doubt in my mind, that only through cæsarean section a living child could have been secured. I knew at the beginning that the uterus contained a large fetus, but this in itself is not an indication for cesarean section. Hirst rightly says (Textbook of Obstetrics, p. 508), "Overgrowth of the fetus is the most difficult condition in obstetric practice to diagnosticate with precision. A careful palpation of the head and body and an attempt to

*Read before the Obstetrical Section of the Eastern Medical Society.

push the former into the pelvic inlet may give one an approximate idea of the relative size of the fetal body and pelvic area, but as a matter of fact the large size of the fetus is usually discovered in practice only after prolonged delay, when attempts at artificial delivery have failed." The early rupture of the membranes by Dr. W. was not a wise procedure, but the doctor was an inexperienced physician and had thus been advised by a neighboring practitioner. Nevertheless I am positive that in this particular case, nothing would have been gained by preserving the membranes, as the fetus could not have been brought through the pelvis alive no matter whether head or feet first.

As stated before, symphyseotomy was not indicated because the additional space obtained through division of the pubic arch would not have sufficed for the delivery of the child, and cæsarean section in addition would have become necessary.

The forceps was tried under the most favorable condition obtainable, but its uselessness was quickly demonstrated. There then remained only craniotomy as a means of delivery, and while I grant both the possibility and probability of a successful cæsarean section at the time when I first saw the patient, I of course could neither foresee nor foretell the outcome of the case and could not advise cæsarean section, which might well have been unnecessary. This case belongs to that fortunately small class, in which the child's life must be sacrificed for the sake of the mother, and I for one maintain that craniotomy to-day and ever will be an operation not only justifiable but necessary in certain cases and under certain conditions.

Case II.—Mrs. R., III- para, age 38 years, consulted me when about seven months pregnant. Two previous confinements difficult, necessitating craniotomy because, as patient stated, children were very large. Pelvic measurements: Sp. ant. sup., 25½ cm., crist. il., 28 cm., trochanters, 31 cm., conjug. ext., 19½ cm., diagonal conjugate about 12 cm. I advised the woman to come to my office in five weeks, and should the child be very large I would end pregnancy before the normal terminus. However, I did not see the patient until ten weeks later, when she was really beyond full term and labor pains had already begun. Examination showed a much distended uterus containing an apparently very large fetus. Breach in fundus, head above the brim. Cervix half dilated, membranes intact. Face presentation with chin pointing to the right iliac synchondrosis. The problem presented was a rather difficult one. Here was a woman with an abnormally large child in utero, which in itself was a probable obstacle to delivery. Besides, the presentation of the face, unless changed, constituted a positive obstruction. Posterior position of the chin demands active interference with a normally developed fetus, for the head may enter but cannot pass through the pelvis. Version in my opinion is the proper treatment. My experience with Schatz's method to convert the face into a vertex position has not been very happy. It usually necessitates the introduction of the hand in utero, and I prefer podalic version as a more simple and efficient corrective operation. In this case I awaited almost complete dilatation, then administered chloroform and turned. Extraction proved very difficult. One arm slipped up in spite of care and baffled the usual manipulation. However, the blunt hook brought it down, after which the head was delivered without difficulty. The child lived and weighed almost thirteen pounds. The recovery of the woman was uneventful.

Case III.—Mrs. L., II- para, age 36 years, was seen in consultation when in labor twenty hours. First labor difficult and protracted, child still-born. Pelvic measurements normal. Uterus contains a large child. Os fully dilated. Membranes ruptured four hours ago. L. O. A. position, head movable above the brim. I gave the opinion that version offered the best chance for the child and but slight danger to the mother, as the uterus still contained a considerable quantity of liquor amnii. There was an apparent disproportion between the pelvis and the child although the dimensions of the former were normal. I was dealing with a pelvis relatively contracted, that is, too small to permit the delivery of a child unaided. Under such conditions version offers undoubtedly the best chance and is both more efficient and sure than the forceps. The latter should not be the operation of choice unless the head has entered the pelvis, when version is of course contraindicated. As, in spite of regular and strong pains, labor did not advance, I performed podalic version. The turning and extracting of the child was comparatively easy, except that the head resisted every effort of delivery. I perforated the after-coming head of the dead or certainly moribund child. The fetus, minus blood and brains, tipped the scale at 12½ pounds, and its probable weight was about 14 pounds.

This case again would have been an excellent subject for cesarean section, provided the difficulties encountered could have been foreseen. Nothing is more uncertain than to determine and foretell the fetal diameters and weight ante or intra partum. To urge and perform cesarean section upon such unreliable evidence is in my opinion a very radical position. The only safe and reliable guide are the external and internal pelvic measurements, and if these measurements are normal or approximately so (with hardly any exception) cesarean section is not indicated. Patients with a prior history of abnormal fetal development should not be permitted to go to full time. If not seen until labor has begun the case should be conducted with extreme care and conservatism. Membranes are preserved until interference has been decided upon, as nothing can be gained by rupturing the bag of waters, but there is increased liability to infection, and version may be made impossible. Symphyseotomy is never indicated, as the slight increase in pelvic diameters is not in proportion to the dangers of the operation. Cesarean section is hardly more dangerous, requires less complicated after-treatment, and abdomen and uterus once opened there is no doubt about our ability to deliver the fetus.

772 Park Avenue.

SPLEENLESS MEN.*

By J. H. CARSTENS, M.D.,
DETROIT, MICH.

That a human being can live without a spleen has been now thoroughly established. At one time it was supposed that the spleen produced the red blood corpuscles or the white ones, or changed the one into the other; but since it is known that the bone-marrow has something to do with the production of corpuscles, and that spleenless men can live in perfect health, more and more operations are being performed for the removal of this organ. However, the spleen is very often removed when the operation can do absolutely no good, and the patient will die as the result of the operation. There are some well-marked indications when splenectomy is justifiable.

In malaria, which often causes enlargement of the spleen, an operation is not indicated, as the organ

*Read before the Mississippi Valley Medical Association, Cincinnati, O., 1904.

will be reduced when the malarial toxæmia is cured. Still, many operations have been performed for this condition, with a mortality of fifty per cent. Splenectomy is seldom justifiable in these cases. Cystic tumors can often be removed without removal of the spleen. Inflammatory conditions and abscesses can often be drained without removing the organ. In leukæmia, the operation should not be done if the red blood corpuscles have been diminished one-half or more; in fact, it is a serious question whether it is often justifiable in such cases, as the mortality is over eighty-five per cent.

Those rare cases of so-called splenic anæmia are cured by splenectomy. The mortality of the operation in these cases is only twenty per cent.

In the case of a floating spleen, I do not think that the removal of a healthy organ is indicated, any more than the removal of a healthy floating kidney. We can stitch the spleen in its place.

Injuries of the spleen furnish quite a list, and removal often affords the only chance for recovery.

In cases of malignant growths, of course the spleen must be removed, provided the growth is not too adherent to other organs. It may be impossible sometimes to make a diagnosis without a microscopical examination, but as a rule the blood examination and the general symptoms will enable us to make the diagnosis.

Case I. Sarcoma of spleen. E. H., aged 32, a telephone line worker; a short, stout young man, who has always been well, and whose family history is negative. He was taken during the winter of 1902 with a distress in the abdomen, followed by gradual emaciation and weakness. He also became anæmic and pale, so that in the course of six months he gave the impression of one suffering from Bright's disease. In the spring an enlargement was noticed in the abdomen, starting on the left side and working downwards, a hard, solid tumor. Dr. John N. Bell was finally called to examine him, and made a diagnosis of an enlarged spleen. He treated him in the usual manner for a few weeks without any improvement, and finally called me. I had him taken to the hospital, and a blood examination was made by the Detroit Clinical Laboratory, with the following report: "Oct. 2, 1902. Erythrocytes, 3,282,688; hæmoglobin, 75 per cent.; color index, 1.15; leucocytes, 11,408; polymorphonuclears, 65.4 per cent.; large mononuclears, 10.8 per cent.; small mononuclears, 25 per cent.; eosinophiles, 0.8 per cent.

"The hæmoglobin is reduced about one-quarter, while the red cells are reduced one-third. The leucocytes are slightly increased in number, but the leucocyte balance is not disturbed. The red cells show marked evidences of degeneration—poikilocytosis and endoglobular changes. A few nucleated red cells were found. The blood has many of the characteristics of a pernicious anæmia, but the count is too high for that condition. The character of the anæmia, together with the presence of the nucleated red cells, leads to a laboratory diagnosis of a severe secondary anæmia, probably due to malignant disease or some long-continued intoxication." Signed, Joseph Sill, M. D.

There was no malaria; the patient never had any; the blood examination also showed there was none. Repeated careful examination of the urine showed no kidney trouble whatever. The blood examination, however, indicated the possibility of a malignant growth. In a man so young it could only be sarcoma, and an operation was urged and agreed to.

Operation October 8th; incision at the outer edge of the left rectus, from the ribs downwards. There were only slight adhesions of the omentum to the spleen, which was easily removed, and the vessels were tied separately and covered with peritoneum. The shock was profound, although he had received two quarts of saline solution by rectum; but the usual hypodermic stimulants revived him. Still, for a week he was quite weak, and his recovery doubtful. He gradually picked up, and in eight weeks he recovered sufficiently to leave the hospital. The spleen weighed four and a half pounds, and the microscopical examination showed a small-celled sarcoma.

During the later part of his stay at the hospital he developed a voracious appetite. This continued for some months. He became very fleshy and strong, with rosy cheeks, and was in every respect a robust man. He follows his vocation, and climbs up and down telephone poles as though he never had been sick. He has remained so to this day. Every three or four months he reports, when I have the blood examined, the last report being the same as that made a year after the operation.

"August 3, 1903: Erythrocytes, 5,500,000; hæmoglobin, 100 per cent.; color index, 1; leucocytes, 7,111; polymorphonuclears, 74.4 per cent.; mononuclears, 25.6 per cent. The blood appears to be practically normal."

Case II. Splenic Anæmia. This case was reported in full in the *Journal* of the American Medical Association, October 1, 1904, and is in short as follows:

Mr. B., aged 38; family history negative; never sick; no malaria or syphilis. Six months previous to coming under observation became anæmic, weak, and incapacitated from work. He complained of distress in the abdomen, which increased in size, and the diagnosis was made of an enlarged spleen. Dr. Peterson brought him to me for consultation. I verified the diagnosis of an enlarged spleen, and had a blood examination made by the Detroit Clinical Laboratory, the result of which was as follows:

"July 20, 1903: Erythrocytes, 3,804,000; hæmoglobin, 75 per cent.; color index, 0.94; leucocytes, 1,250; polynuclears, 10 per cent.; mononuclears, 90 per cent.; eosinophiles, —."

This shows an anæmic condition; the leucocytes reduced to 1,250 and the hæmoglobin reduced enabled us to make the diagnosis immediately.

That peculiar condition was first described by H. C. Wood, in 1871, as splenic anæmia. Reports of quite a number of cases by Osler, Sippy, and others show that this condition is not serious, and sometimes exists for years, generally, however, ending in death as the result of complications. The only cases promptly cured are those operated on. This man was a wreck, and had been subjected to systematic treatment without avail. The only chance seemed an operation.

July 21, 1903, I made an incision, under chloroform, at the outer edge of the left rectus; there were slight adhesions; the spleen was very soft and broke; tremendous hemorrhage occurred; I clamped the pedicle and removed the organ rapidly. I closed the abdominal incision by sutures of dry sterilized catgut. The man recovered from the shock and did fairly well for some days, but had a good deal of nausea; pulse, 110; temperature, from 99° to 100°. The temperature jumped the sixth day to 105°. Blood count, 11,000 leucocytes; sepsis. A stitch abscess was found, which was opened and cleaned. The number of leucocytes dropped the next day to 4,000. There was some delirium during this time, and one day he got up and walked around, when the abdominal incision separated. He was chloroformed and the incision was closed with silk-worm gut sutures. From now on rapid improvement fol-

lowed. The man returned home four weeks after the operation, perfectly well. The last blood examination before leaving the hospital was: Erythrocytes, 3,325,000; leucocytes, 3,000; hæmoglobin, 70 per cent.

He weighed 97 pounds when leaving the hospital. I had him return April 5, 1904, when the following condition of the blood was found: Erythrocytes, 5,448,000; hæmoglobin, 100 per cent.; color index, 1; leucocytes, 9,250; polymorphonuclears, 58 per cent.; mononuclears, 42 per cent.; eosinophiles, —.

His weight has increased to 193 pounds, and he is the picture of health and in every way is well.

These two cases will help to prove the great value of splenectomy in some cases. In modern aseptic surgery the mortality should be low, about that of other abdominal operations that are not septic. The cases also show the great value of blood examination in these obscure cases. The blood examination will enable us not only to make the diagnosis as a rule, but will also point the way to an operation or to non-interference, as the case may be. Sometimes it may not be of much value in other kind of cases, but in diseases of the spleen it is of great importance.

In conclusion I would say:

1. In diseases of the spleen, blood examination must be made.

2. Splenectomy will cure a certain number of cases.

3. Spleenless men can live in perfect health, as we are unable to find any difference between the blood of such men and the blood of those who have not been subjected to splenectomy.

620 Woodward Avenue.

AN EXPERIMENTAL STUDY OF THE MOVEMENTS PRODUCED IN THE STOMACH AND BOWELS BY ELECTRICITY.*

By G. G. MARSHALL, M.D.,
WALLINGFORD, VT.

The animals experimented on were three cats, one rabbit, and one white rat. The stomachs of the cats were full of milk at the time of the experiment; the rabbit's stomach was partially distended with half-digested grass, on which it had been feeding, and that of the rat was filled with food of a semisolid nature.

The currents used were the faradic (two cells), the galvanic (thirty-two cells), and the faradogalvanic. The faradic current was used in varying degrees up to the full strength of the two cells; in using the galvanic battery 32 cells were used, and in the faradogalvanic a mild current was first used, increasing the strength up to the full capacities of the batteries.

The animals were put under the influence of ether, and the mode of making the experiments was then as follows: The hair over the front of the abdomen was cut away and a median incision made through the abdominal wall, exposing the stomach and bowels. First, a moist sponge electrode was applied to the exposed stomach, and the other pole was applied to some indifferent part of the animal's body; next both poles were placed on the stomach, one at either end. A similar application to the bowels was then made. In these and subsequent experiments the three currents—faradic, galvanic, and faradogalvanic—were used consecutively. When the galvanic current was used the current was interrupted and reversed.

Next a small incision was made through the cardiac end of the stomach, just as it appears below the diaphragm. One pole was inserted into the stomach through this incision by means of an insulated copper wire. The other pole, consisting of a damp sponge, was applied to the exterior of the animal's body at different points, and finally was placed directly on the outer surface of the stomach.

By none of these means could contractions be produced in the stomach or bowels, though when the outer pole was placed on the voluntary muscles the latter were contracted.

In some of the experiments the electrode on the interior of the stomach, which I will call the internal electrode, was in immediate contact with the stomach wall, while in others it was in contact only with the stomach contents.

Now the outer sponge electrode was replaced by a metal electrode. This electrode was applied in turn to (1) The outer wall of the stomach, (2) various points on the intestines, and (3) in the rectum.

In the experiment with a metal electrode in the stomach, and a metal electrode on its outer wall, feeble contractions of its pyloric end could be produced, but none at its cardiac two-thirds.

By applying the external electrode to the intestines distinct circular contractions were produced at the point of contact. Where the metal electrode touched the intestines the latter immediately became blanched, and then a somewhat prompt constriction took place, making the bowel look as if it had been ligated by a coarse string, leaving scarcely any lumen to the gut. This constriction would not disappear for several minutes. It was only necessary to make a momentary contact to the bowels, when the contraction would begin and continue after the electrode had been removed. If the end of the electrode were wound with a thin layer of wet cotton no contraction of the bowels would be produced.

With one pole in the rectum, the other electrode still being in the stomach, no movements of either the stomach or bowels could be produced, but the muscles of the back were contracted. The readiness with which the bowel contractions were produced was nearly the same with the faradic, galvanic, and faradogalvanic currents, and the contractions were equally strong with either pole of the galvanic battery.

Next, one of the pneumogastric nerves was cut down upon and isolated from the surrounding tissues. To this exposed nerve the external pole was applied, the other pole still being in the stomach. No contractions or increased peristalsis of the stomach or bowels could be produced by stimulating this nerve.

Finally, another incision was made in the stomach, near the pyloric end, and through this opening the second metallic electrode was inserted, the same as had been done at the cardiac end. Now, with both poles in the stomach, no contractions of this organ could be produced.

The conclusion formed as a result of these experiments is that the stomach and bowels do not readily contract under the direct application of electricity.

While the pyloric end of the stomach feebly contracted, and the bowels contracted uniformly under the immediate application of a small metal electrode, they would not contract when a thin layer of wet cotton was placed over the metal. A stronger current might have produced stomach contractions, but the currents used were stronger than would be employed for therapeutic purposes, and certainly the current would never be directly applied to the stomach or bowels by a metal electrode, as was necessary to produce contractions in these experiments. It

* Read before the Vermont State Medical Society, 1904.

should be made clear that the contractions produced in the bowels had no semblance to peristaltic movements, only the circular fibers being constricted.

Hence we may conclude that electricity, as generally administered, either percutaneously or directly, never causes contractions or increased peristalsis of the stomach or bowels.

Other experimenters have obtained similar results, as will be shown later on, yet many modern writers are of the opinion that gastric and intestinal contractions can be produced by electricity.

Butler, in his work on "Diagnosis," says that the peristalsis may be made more active by electricity, and Edwin Martin, in Hare's "Practical Therapeutics," reports the successful treatment of intestinal obstructions by faradism; one pole over the bowels and the other in the rectum. Kussmaul reports having seen contractions of the stomach in a patient with thin abdominal walls, produced by having one electrode in the stomach and the other held in the patient's hand.

Einhorn and Ewald also believe stomach contractions are produced by direct electrization. I, too, thought I was able to produce contractions of the stomach and bowels, and had so stated in a paper published in MEDICAL RECORD of August 8, 1903.

While making the preceding experiments it was observed that when the external electrode was applied over the front of the chest, the diaphragm and the intercostal muscles were violently contracted, and thus depressed the stomach and liver much below their normal positions.

I believe it is the contraction of the diaphragm that gives the patient the sense of stomach contractions, and in thin persons a visible distention of the abdominal wall, by the pressure downward of the stomach, caused by contraction of the diaphragm, may have been mistaken by some observers for peristalsis of this viscus.

Other experimenters do not believe that the stomach can be contracted by intragastric electricity. Thus Hemmeter, in his work on "Diseases of the Stomach," says: "We do not wish to imply that it is absolutely impossible to contract the human stomach by electricity, but the currents required to effect this must be so strong that the experiment becomes hazardous." Goldschmidt, Manges, and others drew similar conclusions.

Meltzer, in the *New York Medical Journal* of June 15, 1895, reports his experiments on animals' stomachs and bowels by the use of the faradic current. The results of his experiments were very similar to my own, except that he was able to produce more marked contractions of the pyloric end of the stomach by applying the two poles on its outer surface.

Meltzer concludes from his experiments that the mucous membrane of the stomach and bowels, especially of the former, is nearly a nonconductor of electricity, and that it is with difficulty that a current can be passed through it. He says: "A very strong current will finally penetrate the stomach wall," and again he says: "The mucous membrane of the stomach offers the greatest resistance." While he says the stomach muscles are less susceptible to electrical currents, he attributes this in large part to the nonconductive character of its mucous membrane. He states further that by removing the normal membrane from the tongue and placing over this a piece of mucous membrane of the stomach, no contractions of the tongue could be produced.

Hemmeter has stated in his work, quoted above, that the passage of electricity through the stomach may be due to detached particles of mucous membrane.

To determine the conductivity of the stomach mucous membrane, I further experimented as follows, using the faradic current:

1. With one electrode in the stomach and the outer pole applied to the skeleton muscles, the latter always reacted to a (weak) current, essentially the same as though the pole that was in the stomach had been placed on its outer surface, demonstrating that the current had passed through the stomach.

2. The finger was used for the external pole and applied to the outer wall of the stomach, the other pole remaining in the stomach; here the feeblest current was detected by the sensory nerves of the fingers, which would not be possible if the current did not pass through the stomach wall.

3. The stomach was incised along its lesser curvature; its contents were removed, and then the whole organ was lifted out and laid on the abdominal muscles, just to one side of the median incision. One pole was then placed on one extremity of the animal, and the other pole was passed through the incision in the stomach to the mucous membrane of that part of the stomach which was resting directly on the abdominal muscles. When this was done the abdominal muscles beneath responded quickly to every touch of the electrode to the mucous membrane of the stomach, the same as when the muscles themselves were touched, showing that the current passed through the mucous membrane, though the stomach itself did not contract.

These experiments demonstrate to my mind that the mucous membrane of the stomach offers no unusual resistance to electric currents, and that the failure to produce contractions of the stomach is in no way due to a nonconductive character of its mucous membrane.

Since making the above experiments I have further experimented on the human subject, for the purpose of determining if, by the percutaneous method of electrization, any of the currents really entered the stomach. For this purpose I constructed a stomach electrode, having two poles, each pole being connected to a telephone receiver by insulated wires. This electrode is introduced into the stomach, and its two poles being immersed in the fluids of the stomach about three inches apart.

Then by placing the poles of a faradic battery over the stomach, one in front and the other on the back, the make and break of the vibrator was distinctly heard in the receiver, demonstrating positively that the current had entered the stomach.

It will be understood that there was no metallic connection between the telephone and the faradic circuit; that the telephone circuit simply shunted a part of the current flowing through the stomach, and that the presence of the telephone receiver and its electrodes in the stomach could in no way cause the current to flow through the stomach, but simply indicated its presence there.

In making these experiments I was assisted by Dr. J. H. Buffum.

Alcohol and Marksmanship.—In order to determine the effect of alcohol in the power to shoot straight a Swiss battalion was detailed for target practice under varying conditions of alcoholic stimulation. One test was made after total abstinence, another after drinking the previous evening, a third after drinking in moderation on the same day, and lastly, a short time after a heavy drinking bout. The results apparently show that alcohol is helpful to the marksman for short distances and harmful for long ranges.—*The Sun.*

DEFINITION AND CLASSIFICATION OF GASTRIC HEMORRHAGE.

By F. GREGORY CONNELL, M.D.,
SALIDA, COLORADO.
ATTENDING SURGEON, D. & R. G. R. R. HOSPITAL; CONSULTING SURGEON, ST. VINCENT'S HOSPITAL, LEADVILLE.

A WORD to signify hemorrhage from the stomach, or gastric hemorrhage, seems to be lacking in our nomenclature. To be sure there are different terms employed to convey the idea of the vomiting of blood, and the passage of blood per rectum. But there may exist a hemorrhage into the stomach without either of these signs appearing, and on the other hand, either or both of them may be present, with no hemorrhage into the stomach. It would seem, therefore, that the words "gastric hemorrhage" must be employed, as hæmatemesis, gastrorrhagia, and melæna all may give rise to confusion.

Hæmatemesis may present itself in different varieties. That in which the vomiting comes on very suddenly and is very profuse has been dignified by the special and characteristic term, gastrorrhagia. The opposite kind, in which the amount of blood is so small that a very careful examination is necessary to discover its presence, has been termed "occult" by Boas.

Melæna, or morbus niger, as originally employed by Hippocrates, likewise signified the passage of blood either per os or per anum, but in this instance the blood was dark in color, it being originally supposed to be of venous origin. Aretæus was the first to point out that such blood was not of necessity venous, and that arterial blood, if acted upon by the gastric or intestinal juices, would soon have this same dark color. At the present writing the term melæna signifies the escape of blood through the intestinal canal.

Generally speaking, melæna, without the clinical history, may be disregarded in considering gastric hemorrhage, on account of its late appearance, and the inability to differentiate that arising from the stomach, and that originating in the bowel. With the clinical history, at times, it may be of great value. Although gastric hemorrhage may occur without hæmatemesis, still this is the only reliable, substantial, and practical sign of this occurrence. Therefore a study of gastric hemorrhage must necessarily be one of hæmatemesis.

To aid in the study of this symptom it will be convenient to make various divisions and sub-divisions of the subject. First into chronic and acute, as has been emphasized by Moynihan. These two varieties of hæmatemesis can usually be differentiated with ease, and the necessity of doing so in all reports of cases is urgent, so that a proper understanding of the conditions may be arrived at.

The main differential feature between these two varieties of stomach hemorrhage is that chronic hæmatemesis has not been looked upon as a clinical entity, but merely as one of the symptoms of some gastric pathology, usually ulcer. It is always moderate in amount and repeated at longer or shorter intervals. And while the acute hemorrhage is still a symptom, it is one of such magnitude as to become the all important condition, demanding immediate attention, and for the time being completely overshadowing the pathological lesion of which it is but a symptom.

Chronic hæmatemesis includes all forms of hemorrhage from the most insignificant, such as the occult, to one that can be with difficulty differentiated from the acute form. The ordinary type of chronic hæmatemesis has been very succinctly described by Moynihan, as the hemorrhage from a chronic ulcer, as follows: "The onset after a long history of digestive disturbances culminating in acute discomfort for a few days, the tendency to recurrence, with brief intermission of a few hours or a day or two, the moderate quantity of blood ejected in each outbreak, and the condition of anæmia produced by the repeated loss of blood."

While such an hæmatemesis is usually characteristic of a chronic ulcer, similar hemorrhages may occur from other conditions, and neither is it the only variety of hemorrhage from such an ulcer. It should be remembered that an acute hæmatemesis may spring from a chronic ulcer, but that the more usual source is an acute ulcer or erosions.

The same author characterizes the hemorrhage from an acute ulcer as follows: "Spontaniety, abruptness of onset, the rapid loss of a large quantity of blood, the marked tendency to spontaneous cessation, the infrequency of a repetition of the hemorrhage in anything but trivial quantity, and the transience of the resulting anæmia." This is typical of the acute hemorrhages, but is not confined to acute ulceration of the stomach. It may occur as a result of conditions other than ulcer, or during the course of a chronic ulceration.

Acute hæmatemesis may be further divided into symptomatic and nonsymptomatic, and as either of these may occur only once or be repeated, they may be again divided into single and multiple.

By symptomatic is meant an acute hæmatemesis which follows after a longer or shorter period of time, a history of some gastric affection which may or may not have included chronic hæmatemesis.

By nonsymptomatic is meant an acute hæmatemesis that occurs without the existence of any persistent or prominent prodromes. The latter is usually due to an acute gastric ulceration or an erosion, and the former generally comes from a chronic ulceration. The necessity of such a differentiation, whenever possible, from the standpoint of prognosis and treatment, is plainly of vast importance.

The term idiopathic might have been employed instead of nonsymptomatic, were it not for the danger of confusing this symptomatic use of the word with the pathological use, as employed by many to denote that form of hemorrhage from the stomach, in which, at autopsy, no plausible causative factor can be discovered.

The subject of hæmatemesis, therefore, may be outlined as follows:

- Hæmatemesis
  - Chronic
  - Acute
    - Symtomatic
      - Multiple
      - Single
    - Non-symptomatic
      - Mutiple
      - Single

This schematic presentation of gastric hemorrhage, and especially that of acute hæmatemesis, reveals a very complex subject, and one that is apparently in need of farther study, despite the very able and most complete monographs already published.

This fact will be again emphasized by a brief outline of the possible previous and after history of an attack of hæmatemesis.

As to the antecedents; it may follow: (1) an absolutely negative history; (2) a history of gastric ulcer (*a*) with hemorrhage, (*b*) without hemorrhage.

As to the outcome; it may terminate in (1) Perfect recovery after (*a*) a single hemorrhage, (*b*) repeated hemorrhages. (2) Imperfect recovery, with symptoms of ulcer (*a*) without hæmatemesis, (*b*) with hæmatemesis. (3) Death after (*a*) a single hemorrhage, (*b*) repeated hemorrhages.

A CASE OF SCIATIC NEURITIS WITH PARALYSIS FOLLOWING MALARIA.

By WILLIAM GEORGE RUSSELL, M.D.,
NEW YORK.

The following case may not be very rare, but it would seem to be one of more than ordinary severity. Mr. A., occupation postmaster, age 38 years, family history negative, save that father had two attacks of probably simple melancholia. The patient, prior to the present illness, three months since, had always been well, excepting two or three regular ill spells during August of each year, when he had some intestinal trouble for a short time only. This illness began with severe epigastric pain, later extending down the abdomen. He was seen once by a physician, who told him he thought he had grippe. Improvement followed this physician's prescription. Two or three days later intense headache began, accompanied by slight elevation of temperature, extreme restlessness, apprehension, and depression. I saw him then for the first time. I gave morphine to relieve the head symptoms, and told him I would see him later. Some hours later I called and found the headache decidedly relieved, a temperature two or three degrees above normal, nothing else unusual, excepting his fear of brain fever. I gave him calomel, followed by a saline. This acted well, and he also vomited a large quantity of bile. He seemed then decidedly better. Some hours later pain began in the lower part of the back, extending very moderately to the legs; the high temperature continued. This condition lasted for a few days. A diagnosis of remittent malarial fever was made, and I began giving large doses of quinine, alternating every few days with calomel. This gradually modified and controlled the pain. At the end of about a week or ten days I left him, apparently convalescent. He called me again, with complaint of intense pain in the thighs and down the legs, especially in the left thigh. There were no girdle pains. I examined him very carefully this time; the pupillary reflexes were normal, also the patellar; there was slight tenderness of the spleen, but there were no abdominal symptoms or anything else unusual. I was forced to resort to hypodermic injections to relieve the pain, and gave the quinine in larger doses. The pain continued most severe along the sciatic nerve, especially of the left leg; the patient was very restless and had mild delirium at night; there were no bladder symptoms, excepting an occasional retention of urine, which I attributed to the morphine and to the patient's highly nervous condition. Urinary examination was normal in its results. This condition lasted for ten or twelve days, the patient getting no relief, excepting for a few moments at a time, from counterirritants, hot packs, massage, and various other treatments. About this time the patient found he could not use his left leg, and his right not as well. Both the patellar reflexes were lost, the pupils were normal; the pain in the left leg especially was so intense that he could not rest, and had to be moved every few moments, and could get no relief, excepting from the hypodermics of morphine. This I now discontinued, as I did not wish the patient to become dependent on it. The condition of the patient remained unchanged for about ten days, at which time he began to receive vibratory massage. After the first application of this along the dorsal and lumbar nerves and down the thigh, over the muscles, and along the sciatic nerve, the pain disappeared, but returned again with less severity. Similar treatment given each night for about ten days was followed by gradual improvement in the patient; he had less pain, some use of the right leg, which had been similarly affected, but in a more moderate degree than the left. He could now sit up for an hour or two a day, but was unable to walk or use his left leg at all. In order to change his environment, as his business gave him much worry, I sent him away a short distance to a private sanatorium, where he was given baths and massage. He has gradually improved up to the present time, has absolutely no pain, is able to use his right leg, and to drag or push the left one along if he is helped on either side. The patellar reflex in the right leg is normal; that in the left is still absent. There was some atrophy of the muscles below the left knee.

71 East Fifty-second Street.

The Genesis of Insanity.—J. Montgomery Mosher outlines in a most vivid manner the steps of exhaustion of the nervous system. He states that the dominating influence in resisting disease is that of the nervous system. A healthy nervous system gives the greatest immunity. "Nervous exhaustion" is termed the "American disease," but only, as the author declares, because in America has been anticipated the stress of life which is rapidly becoming universal. Ambition is one of the most potent causes of nervous breakdown. In immigration is seen a most striking illustration of the hazard risked for personal improvement. The colonization of alien communities in the large cities of this country is "a menace to the physical, social, moral, and political security of the country." Nearly 70 per cent. of persons admitted to the hospitals for the insane for the fourteen years ending 1901 were of foreign birth. But this calamity does not befall the foreign population only. The country-bred boy and girl who leave the fresh air, good food, and free life of the parental farm, come to the city and are overpowered by its strenuous life. The first sign of nervous exhaustion is perverted sensation. Within normal limits this is fatigue, and rest relieves it. When this limit is overreached rest is no longer recuperative and irritability develops. This is the first pathological step Sensory symptoms follow fast—tingling, numbness, formication, hot or cold flashes, and pain. Migraine and neuralgias are common. Motor anomalies appear early. Tremors, twitching, and peripheral spasms occur. The sensory and motor symptoms are associated with morbid mental states. Worry and loss of memory are complained of. Investigation shows that the sources of worry are inadequate, and the loss of memory is rather a defect in concentration. Disturbances of digestion, dyspnœa, and palpitation form the basis of hypochondria. If the patient is a woman, the gynecologist is consulted. The manner of the patient changes. Mistakes are made. The crisis occurs. Rambling speech and violent action suddenly surprise the patient's friends. Various diseases may be simulated at different periods. The keynote of the treatment of nervous exhaustion is rest. The treatment should always be recuperative and reconstructive. Long journeys, amusement, and so on are detrimental by using up nervous force. Simple, nutritious food should be given. Autointoxication should be combated by keeping the excretory organs active. Electricity, massage, and passive movements are often indicated. Later, active exercise may be indulged in. At least four pints of water should be taken daily, and this should be measured. Plunge baths are very beneficial. Within a few months color, weight, and strength return, but vigor is still wanting. The patient tires rapidly. Care and moderation must be exercised for at least a year in order to avoid relapse. The physician has scored a victory, but he must not cease his vigilance. He must determine the amount of work that his patient can do without injury to himself. He must determine the danger point, and even if his investigations seem to pry into the intimate history of the patient, his courage must not fail, for this is a part of his duty. He must establish the relations of the individual with his environment, for it must be remembered that "it is not given to man to surpass his destiny."—*Albany Medical Annals.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 7, 1905.

DR. FOSTER'S JUBILEE.

ON the last day of the year 1904 Dr. Frank P. Foster rounded out a quarter of a century of editorial control of the *New York Medical Journal.* This is a record of professional editorial headship which has been surpassed in this country only by Dr. Shrady, who guided the MEDICAL RECORD for thirty-eight years, and by the elder Dr. Isaac Hays in his management of the *American Journal of the Medical Sciences*, from its foundation in 1820 to his death in 1879. Dr. Foster became editor of the *New York Medical Journal,* then a monthly publication, in January, 1880, and has therefore controlled its policy for twenty-five of the forty years of its existence.

Every journal, like every individual, has a special character of its own, and Dr. Foster's paper is no exception to the rule; in its scientific bearing, its conservatism, and its dignified and ethical treatment of the questions of the day it has always mirrored faithfully the personality of its editor—a man so well known to the medical profession of this country that any attempt at a characterization of him would be superfluous. A cordial friendship always existed between him and the former editor of the MEDICAL RECORD, and this amity has ever been, and we hope always will be, reflected in the relations of the two journals. To Dr. Foster, as the dean of medical journalists in America, we offer our sincere congratulations on this termination of his quarter centenary in the conduct of the *New York Medical Journal* (his career as a medical editor covers a much longer period of usefulness), and we join with our colleagues of the medical press in wishing him yet many years of honorable devotion to the cause of medical literature.

THE NASAL TREATMENT OF ASTHMA.

ASSUMING the accuracy of the author's observations, the paper by Dr. Alexander Francis, in the *Journal of the Royal Army Medical Corps* for November, is of considerable interest. Since the days of Aurelian the association of asthma and nasal disease has been noticed, but not until Voltolini, in 1871, published 11 cases of relief by removing nasal polypi, was any great attention paid to it. Later, many observers recorded successful results from nasal treatment, and the belief in the nasal origin of asthma gradually gained ground, until Bosworth, of New York, stated, in 1886, that "a large majority of, if not all, cases of asthma are dependent upon some obstructive lesion in the nasal cavity." In 1889 he published a list of 46 cases of asthma, of which 28 were cured and 12 improved by intranasal treatment. Later he reported 86 cases of asthma, of which 42 were cured and 33 improved. In Schmiegelow's 50 cases of asthma, 32 were cured and 11 improved. But among the 32 cures, asthma recurred in 17 cases, with a recurrence of the nasal lesion. In the 53 cases treated by Heyman, 29 were cured and 14 improved. Lubinski, on the other hand, only claimed to have cured 27 and improved 13 out of 143 cases of asthma with nasal and pharyngeal lesions. Bosworth's belief that the majority of cases of asthma have some nasal lesion has been strongly combated, and Francis thinks that the general opinion among physicians now is that even when nasal trouble is found, little hope of obtaining permanent relief can be expected from nasal treatment. Most of the recent text-books on medicine merely mention that the nasopharynx needs attention if any gross lesion is found, but hope of relief is based chiefly on climate, diet, and drugs.

No one has suggested nasal treatment in the absence of obvious disease, yet actual experience has shown Francis that, paradoxical as it may seem *a priori,* it is just those cases without obvious lesion that are benefited or cured by nasal treatment, and that the only cases in which a poor prognosis must be made are those associated with such gross lesions as polypi. In the author's series of cases, of a total of 402, the nose was apparently normal in 346. In only 18 was no relief or but slight relief obtained, to which we may add 17, of which no record was made. The criticism that the rhinologist is apt to be deceived because he is consulted only when sensible nasal disease exists, does not apply to his series as the great majority of his cases came to him because he was known to treat asthma, not because he practised rhinology. His experience has led him to believe that asthma is a reflex bronchial spasm; that the initial irritation may be in the nose; that it is not directly due to any mechanical obstruction of, or any gross lesion in, the nasal passages; and that some part of the nasal apparatus has a controlling influence upon the respiratory center. The author then takes up these propositions seriatim, and fortifies his position by a goodly array of case excerpts. Nearly every case he has seen has tended not only to confirm the bronchial-spasm theory of asthmogenesis, but also the author's belief that the spasm is of reflex origin. That the irritation may originate in the nose is indicated by the intimate association between hay fever and asthma, the very common record of excessive sneezing at some period in the previous history of an asthmatic patient, and the not infrequent alternation between asthma and sneezing. He cites a number of cases to sustain his contention, *e.g.* two of immediate onset of asthma after fracture of the nose, with cure from nasal treatment; also two cases in which touching the septal mucous membrane provoked instant bronchial spasm ("It felt as if you were screwing my chest up in a vise").

That asthma is not directly due to mechanical obstruction and is not commonly caused by gross lesion is, Francis considers, proven by his and other case series. Polypus, he thinks, merely coexists with asthma and does not cause it. He cites a striking case, in which the two conditions being combined, and the patient being "a perfect wreck," believing he could do no good, he merely cauterized

the septum. The result was that three years later the patient reported entire freedom from asthma, except for a very slight attack after a very long journey; the polypus, of course, persisting. This was the only case out of thirty-two similar ones of coexistence of the two conditions in which permanent relief was obtained. Francis also emphasizes the non-correspondence between patency of the air-passages and relief of asthma; for example citing cases in which the asthma was intensified after the removal of obstructive polypi.

The author concludes by saying that there is an asthmogenic zone on the septum nasi, by treating which one is able in the great majority of cases to relieve all bronchial spasm, and that we need not any longer take the view of an eminent authority that the asthmatic's only hope lies in potassium iodide.

QUININE AMAUROSIS.

The type of blindness subsequent to the ingestion of quinine is far less common than that known as wood alcohol blindness. According to Dr. Angus McGillwray, who writes on the subject in the *Scottish Medical and Surgical Journal* for November, there are only about one hundred cases of quinine amaurosis on record. In practically all the cases recorded, the drug has found its way into the system through the stomach. The toxic dose of quinine varies in man from fifteen grains to an ounce a day. Idiosyncrasy and a marked neurotic temperament are important factors in the production of quinine amaurosis. It is doubtful if there is any racial immunity, but the affection would seem to be much more prevalent among men than women.

Quinine blindness is invariably bilateral. In mild cases, the defect in vision is said to be limited to temporary amblyopia, but in severe cases the blindness is invariably complete, and is ushered in with great suddenness. The intensity of the blindness is more marked than in any other form of toxic amblyopia, in which recovery is possible, and the blindness is accompanied by extreme pallor of the optic discs and ischæmia of the retina from contraction of the retinal blood-vessels through spasm, together with contraction of the fields of vision. Other symptoms are diminution of the color and light sense, dilatation and immobility of the pupils during the acute stage, diminished accommodation, ptosis, nystagmus, and occasionally divergent strabismus.

De Schweinitz describes the pathology of the disease as follows: "In the earlier stages of the blindness, *i.e.* from the first to the fourth week (ophthalmoscopically pallor of discs and great contraction of vessels), the microscope reveals in the optic nerves imperfect differentiation of the fibrous trabeculæ and a spreading apart of the individual nerve fibrils, which are beaded and varicose, and beginning to be atrophic. At this time no marked changes are present in the vessels. There is no evidence of neuritis. Later, *i.e.* from one to three months after the onset of the blindness (ophthalmoscopically white discs and practically complete obliteration of vessels), there is nearly complete atrophy of the optic nerve fibers, thickening and collapse of the nutrient arteries of the optic nerve, increase in size of the perivascular lymph spaces, and occasionally partial obliteration of the central vessels of the nerve with a partly organized thrombus. The atrophy extends throughout the nerve, chiasm and tracts. Even in sections of the nerves, which ophthalmoscopically give every evidence of atrophy, and which under the microscope show extensive atrophic changes, certain fibrils still remain unaffected, and, singly or in patches, stain somewhat imperfectly with the Weigert and Weigert-Pal reagents. This probably explains why vision is sometimes retained, even when the degenerative process appears complete. It is analogous to the retention of unaffected nerve fibers within the atrophic areas of the papillomacular bundle in cases of alcohol and tobacco amblyopia."

Other investigators differ with regard to the pathogenesis of quinine amaurosis, but the lesion is undoubtedly a peripheral one.

Concerning treatment, Dr. McGillwray says that during the acute stage of the disease, good results have followed inhalations of nitrite of amyl, and the internal administration of digitalis. Strychnine is undoubtedly of service, if we are to judge by the recorded cases so treated, and galvanism has found an advocate in Buller.

One Hundred Years of Publishing.

Under this title Messrs. William Wood and Company have issued a brochure recounting briefly the history of the house since its foundation in 1804 by Samuel Wood, who opened a book-shop that year on Pearl street, in this city. With the exception of the Methodist Book Concern, this is the oldest publishing house in New York city, and throughout its existence the management has remained in the hands of one family—a fact worthy of remark in this country of frequent business changes. Soon after opening his store Samuel Wood set up a small printing press and began to publish primers and other little books for children. The first of these publications, issued in 1806, was called "The Young Child's A B C, or First Book." In the course of time the sons and sons' sons were one after another taken into partnership as the elders retired, and under the influence of William Wood and of his son, the senior member of the present firm, the business of the house became gradually specialized in the direction of medical publications. This interesting historical account of the house of William Wood and Company is illustrated with pictures of the quarters occupied by the firm at various times, as the growth of the city drove them gradually farther up town, and with portraits of the successive heads of the house.

Percussion.

Sir W. T. Gairdner, formerly Professor of Medicine in the University of Glasgow, writes in the November number of the *Edinburgh Medical Journal* on the methods of percussion, with special reference to the importance of minimizing the stroke in most cases in the delimitation of areas. The manner of delivering the stroke in percussion differs to an appreciable degree in Edinburgh and Glasgow, and Professor Gairdner discusses the point as to which is the better mode. He quotes largely from an article by himself, which appeared in the *Medical Times and Gazette* of December 19, 1888. In this article attention was drawn to the fact that most persons—and almost all beginners—in employing percussion for the delimitation of organs, err by percussing too hard. The carefully minimized stroke gives approximately exact definitions, while the stronger stroke necessarily gives less exact, or

wholly inexact, limits of dull and clear areas under like circumstances. The writer criticises to some extent the methods of Piorry, the great master of mediate percussion, who proceeded throughout on the assumption that percussion operates directly downwards, or in the direction only of the impact, in the way of educing the characteristic sound. He thinks that Piorry left a legacy of fatal confusion to his successors, by teaching that for every organ or structure in the body there was a process of delimitation of its deeper relations, which he implicitly regarded as equally available for exact definition with the superficial. In short, Gairdner does not believe that the best means for deep percussion is simply a stronger percussion stroke, but holds that this so-called deep percussion is necessarily inexact percussion.

He describes his method, which he terms a carefully minimized percussion stroke, as follows: "You are to percuss so as to elicit the distinctions of sound depending on air-filled or not air-filled viscera when superficially placed in reference to the abdominal wall; but you are not, as a rule, to strengthen your stroke beyond what is absolutely necessary for this purpose, at least when you are in search of objects such as the thin edge of the liver, which closely underlies the surface, or rather, the wall of the abdomen." Gairdner deprecates the use of Wintrich's hammer—although he himself used it for some years—because it has the effect of cultivating a habit of too strong, and therefore inexact, percussion. . In his opinion a carefully minimized stroke is essential to correct practice, and he thinks that it is vain to expect really accurate results unless this condition is systematically attended to. He is especially emphatic in his contention that for teaching purposes beginners should be started in the right line, and not involved in the intricacies of a terminology which is itself demonstrably out of accord with the laws of acoustics.

Actinobacillosis *vs.* Actinomycosis.

An article on the first of these conditions forms the substance of Bulletin No. 1 of the Health of Animals Branch of the Canadian Department of Agriculture. The two conditions above named were confounded until 1900-1, when Lignières and Spitz, by exhaustive work, showed that besides the well-known "lumpy jaw," caused by the streptothrix, a bacillus having none of the characters of the latter was responsible for the production of lesions which exhibited the same general characteristics as those of actinomycosis, with the exception of their microchemical characters. In 1902 Nocard showed that the disease was widely spread in France. The disease as found in Canada by the author, Dr. C. H. Higgings, is identical with the disease in France and Argentina, but in Canada it exists in an attenuated form. The extent of the disease in Canada has not been ascertained, but it is probable that a number of the cases hitherto ranged under actinomycosis would on investigation prove to be referable to actinobacillosis.

The author saw four cases, all in cattle. The gross lesions are very similar to those of actinomycosis, and consist of a connective tissue hyperplasia. In many instances the lesions can be differentiated from those of actinomycosis only by staining methods, particularly Gram's method, which involves decolorization of the preparations upon treatment by alcohol. The pus is characteristic, being semi-solid, glutinous, almost transparent, and containing whitish granules scarcely visible to the naked eye, which under the microscope exhibit "bizarre" forms and under high powers show the peculiar bulb-like processes radiating from the mass. The bacillus resembles in a marked degree that of fowl cholera. It is aërobic (facultative anaërobic), non-motile, and usually measures 1-1.8 by 0.4-0.6 microns. It stains with the ordinary anilins (especially the acidified), but decolorizes by Gram. It agglutinates with the serum of infected animals. Guinea pigs intraperitoneally inoculated died in from nineteen to thirty-one days with generalized actinobacillosis, but without the development of peritonitis. They presented post mortem the characteristic lesions. Rabbits also succumbed under the same conditions.

The treatment as far as is known consists in the administration, as in actinomycosis, of large doses of potassium iodide. While beneficial, this treatment will, however, have no ultimate results unless adopted in the early stages of the disease. This is easily understood when it is remembered that from the location of the lesions in the large majority of cases in the region of the larynx and from the extensive tumor formation respiration is seriously interfered with, whereby the condition of the animal soon becomes such as to render treatment an unprofitable venture.

A Regiment of Health Officers.

At the coming meeting of the Pennsylvania Legislature a bill will be introduced providing for the better protection of life and health in the several counties and townships of the commonwealth by the establishment of county boards of health and county and township health officers, and for the notification by physicians of contagious diseases, with penalties for failure to comply with the provisions of the act. It is contemplated that the State Board of Health and Vital Statistics shall appoint in each county a practising physician of at least five years' experience, who shall have special knowledge of sanitary law and administration, to be the medical officer of the county. The health officer who is to serve in each township will be named by the County Courts, subject to the approval of the State Board of Health. This auxiliary organization to the State Board will comprise 1,500 physicians, each having the authority of a constable as to making arrests and that of a justice of the peace as to taking testimony and summoning witnesses. The object of organizing such a force of experts is to patrol the entire State, with the view of preventing epidemics such as have in the past devastated numerous communities. These health officers will have full power to investigate water supplies and distribution, drainage, pests of every description, as well as ordinary nuisances. Through frequent reports from these officers the State Board of Health will be kept in close and constant touch with the sanitary condition of every section of the State and have cognizance of the entire water supply, which will be kept under special observation. The medical officer of health, together with the township health officers and the county commissioners, will constitute the County Board of Health. Each County Board will meet once a year, unless called together more frequently by the county health officer, who is vested with power to call such meetings whenever necessity shall arise. These officers shall receive for compensation from $100 to $500 a year, with six cents for mileage. These charges are to be paid by the counties and are to be adjusted in proportion to the population. The county medical officer of health shall be the salaried secretary and executive officer of the board, and it will be his duty to notify immediately the secretary of the State Board of the exist-

ence of any case of smallpox, diphtheria, scarlet fever, typhoid fever, or cholera, or of an epidemic of any communicable disease affecting either human beings or domestic animals within the county in which he has authority. He will have power to issue notices for the abatement and removal of all nuisances and to enforce the same. Citizens may file with these health officers notices of infectious diseases and concerning nuisances, and have the same investigated without cost.

Spontaneous Recovery From A Cerebral Tumor.

A neoplasm, once developed, rarely disappears without surgical or other form of physical removal. Tuberculomata and syphilomata may break down and even be absorbed, either spontaneously or as a result of therapeutic measures, but these are not in the strictest sense of the term true new-growths. Nevertheless, other varieties of tumor-formation may occasionally undergo degeneration of one kind or another, and thus be gradually removed. An interesting case of recovery from tumor of the brain has recently been placed on record by Dr. George E. Rennie (*Australasian Medical Gazette*, September 20, 1904). Of course, as there could be no physical demonstration, the diagnosis must for the present be considered as lacking confirmation, while, on the other hand, the recovery may prove not to be permanent, although, at the time of the report, a period of more than two years had already elapsed without recurrence of symptoms.

The patient was an unmarried ship-steward, 31 years old, with a history of gonorrhœa, but none of syphilis, who two years before coming under observation had fallen a distance of twelve feet, striking the head. Though stunned, he was apparently but little injured, and he speedily recovered without ill effects. After two years severe occipital headache set in, and weakness and staggering developed. There was some difficulty in walking and speaking. The pupils were dilated, the right being slightly the larger. Both at first reacted sluggishly to light, but not in accommodation, although later the reaction to light also was lost. There was some diplopia. Each eye exhibited early optic neuritis, the more pronounced in the left. There was some dysphagia, but no vomiting and no alteration in sensibility. The knee-jerks were exaggerated and the Babinski reflex was present, although ankle-clonus was absent. There was general tenderness of the scalp, especially marked in the occipital region. After potassium iodide had been administered for some two weeks without improvement a trephine-opening was made in the left parietal bone. No excess of fluid was found in the ventricle, but the headache was for a time greatly relieved, although speech became thicker and the eyesight was not improved. The senses of hearing and smell were normal. There was slight ptosis of both upper eyelids. The vertical movements of the eyeballs were defective, while the lateral movements were good, though with some coarse nystagmus and some divergence of the visual axes. There was slight weakness of the muscles on the left side of the face. The mouth could be closed feebly and the tongue protruded only a short distance. The man was able to drink, but could swallow solids only with difficulty. The sphincters were not affected. The temperature was normal, the pulse 100. The heart was free from lesion, the urine normal. A diagnosis was made of tumor at the base of the brain and again potassium iodide and mercuric chloride were prescribed. The patient, however, continued to grow worse, and this medication was withdrawn in the course of three days, while morphine had to be administered for the relief of the headache. Finally, contrary to expectation, he began to show signs of improvement, which gradually went on to practical recovery.

The onset and the evolution of the symptoms in this case are reasonably referable to a chronic progressive lesion, most probably a neoplasm of some kind at the base of the brain, and not to a vascular or an inflammatory lesion. The actual nature of the neoplasm must remain in doubt, although syphilis tubercule, or some benign growth, perhaps cystic, suggests itself; but syphilis, probably a gumma seems the most likely.

News of the Week.

The National Association for the Study and Prevention of Tuberculosis.—The first annual meeting of this association will be held in Washington, D. C. at the New Willard Hotel, on Thursday and Friday, May 18 and 19, 1905. There will be general sessions, and division of the work into the following three sections: 1. *Sociological.*—Chairman, Mr Homer Folks, New York; Secretary, Miss Lilian. Brandt, 105 East Twenty-second street, New York: Executive Committee, H. M. Bracken, St. Paul: J. W. Brannan, New York; E. P. Bicknell, Chicago; Ed. T. Devine, New York; Chris. Easton, Newport: Irving Fisher, New Haven; John S. Fulton, Baltimore; F. L. Hoffman, Newark; J. N. Hurty, Indianapolis; S. A. Knopf, New York; Ernest Wende, Buffalo; A. M. Wilson, Boston. 2. *Pathological and Bacteriological.*—Chairman, Dr. Mazyck P. Ravenel, Philadelphia; Secretary, Dr. D. J. McCarthy, Phipps Institute, Philadelphia; Executive Committee, Ed. R. Baldwin, Saranac Lake; Wm. T. Councilman, Boston; Wm. T. Howard, Jr., Cleveland; Hugh M. Kinghorn, Saranac Lake; Wm. G. MacCallum, Baltimore; Roswell Park, Buffalo; Wm. H. Welch, Baltimore. 3. *Clinical and Climatological.*—Chairman, Dr. Norman Bridge, Los Angeles, Cal.; Secretary, Dr. S. G. Bonney, Stedman Building, Denver, Colo.; Executive Committee, Robert H. Babcock, Chicago; Frank Billings, Chicago; Vincent Y. Bowditch, Boston; Lawrason Brown, Saranac Lake; J. P. C. Foster, New Haven; Chas. L. Greene, St. Paul; Ed. C. Janeway, New York; H. M. King, Liberty, N. Y.; Arnold C. Klebs, Chicago; H. R. M. Landis, Philadelphia; Chas. L. Minor, Ashville; J. H. Musser, Philadelphia; Ed. O. Otis, Boston; Wm. B. Stanton, Philadelphia; A. Stengel, Philadelphia; Joseph Walsh. Philadelphia; James C. Wilson, Philadelphia.

The American Association for the Advancement of Science held its fifty-fourth annual meeting in Philadelphia during the Christmas holidays. The meeting was opened by the retiring president, Mr. Carroll D. Wright, who was succeeded in the chair by Prof. W. G. Farlow, of Harvard. The vice-presidents elected, who are the chairmen of the various societies forming the association, were Prof. Alexander Zwiet, University of Michigan; Prof. W. F. Magie, Princeton; Prof. L. P. Kinnicutt, Worcester Polytechnic Institute; Prof. D. S. Jacobus, Stevens Institute; Prof. Eugene A. Smith, University of Alabama; Prof. C. Hart Merriam, Department of Agriculture, Washington; Prof. B. L. Robinson, Harvard; Dr. Walter Hough, National Museum, Washington; M. A. Knapp, Chairman of the Inter-State Commerce Commission, and Prof. H. P. Bowditch, Harvard.

A Luncheon to Dr. Foster.—On Saturday, December 31, a luncheon was given at the Hardware Club by Mr. Elliott, of the A. R. Elliott Publishing Company, in honor of Dr. Frank P. Foster, to com-

memorate the completion of his twenty-fifth year as editor of the *New York Medical Journal.* The guests included the staff of the *Journal,* colleagues in the medical press, and intimate personal friends of the guest of honor.

Dr. Emily Dunning, the first, and, as yet, the only female ambulance surgeon to do service in this city, recently completed her term of service on the house staff of Gouverneur Hospital, and was presented with a set of complimentary resolutions by the attachés of the hospital. Soon after her retirement she married Dr. Benjamin S. Barringer, a former classmate in the Cornell Medical School, and together they have gone to Vienna to continue their studies.

Dr. Robert S. Woodward, who has been chosen head of the Carnegie Institute, has been dean of the School of Pure Science at Columbia University since 1895, and Professor of Mechanics and Mathematical Physics since 1893. He was born in Rochester, Mich., on July 21, 1849, and graduated from the University of Michigan in 1872. He was for a time in the astronomical and geodetic survey service, and is the author of several technical publications under the Smithsonian Institution.

Dr. Frank H. Lamb, of Glendale, O., has been appointed assistant to the Chair of Physiology, Harvard Medical School.

Dr. Edwin Sternberger has been appointed assistant visiting physician to the fourth division of Bellevue Hospital.

Dr. W. W. Bostwick has resigned as medical officer of Sailors' Snug Harbor, where he has served over seven years, to enter upon private practice.

Tuberculosis in the Tenement Districts.—Thomas C. F. Crain, Tenement House Commissioner, in his annual report to Mayor McClellan, demonstrates that the tuberculosis statistics of certain portions of the city are little short of appalling. Of forty-eight blocks in the Thirteenth Ward in Manhattan Borough there were only seven in which there were no deaths from tuberculosis during 1904. In several blocks there were as many as twelve deaths during the year, and in others there was an average of eight. Altogether, there were 187 deaths from tuberculosis during the year in this ward, which is bounded on the north by Rivington street, on the east by East street, on the south by Grand and Division streets, and on the west by Norfolk street. The ward contains 874 tenement houses, with a population of 12,008 persons. There were 516 cases of contagious diseases in this district last year, with a total of 571 deaths from all causes during the same period. The indifference of property owners to the welfare of their tenants is shown by the fact that last year 84,938 violations of the law were filed against landlords, an increase of 24,439 over the figures of the year before.

Hospital News.—The general prosperity has been reflected this year in a notable increase in the amount of the collection on Hospital Saturday and Sunday, the returns indicating that the deficit of last year will be more than made up in this. St. Thomas's, which last year fell from $2,700 to $1,700, now reports that more than $5,000 was collected, with several absent pew holders still to be heard from. Advances over last year are also reported from the trade auxiliaries, especially those collecting among bankers and the dry goods, clothing, and kindred trades. Collections on the exchanges are also making most favorable progress.

Cook County (Ill.) Hospital Staff.—A meeting was recently held by the Commission to select members of the County Hospital medical staff, and to adopt a report made by its special committee. It is proposed that nervous and mental diseases be established as a separate department of service; that the apportionment of the eclectic and homœopathic members of the staff in the departments be left to the decision of the representatives of those schools of medicine, and only in case they cannot agree that the nominating commission decide. All applicants must be citizens of the United States and residents of Cook County for at least five years, and in practice or study for at least five years after graduation. The following regular departments of service are to be created, with the number of attendants for each as indicated: Surgery, 12; medicine, 12; nervous and mental diseases, 4; diseases of children, 6; obstetrics, 4; skin diseases, 2; diseases of the eye, 2, and diseases of the ear, nose, and throat, 2. Seven committees were appointed to pass on the applications, one for each department. These committees are composed of physicians.

Staff for the Children's Memorial Hospital.—The following physicians were chosen for the medical staff of this institution at a recent meeting of the Board of Directors: Drs. Fernand Henrotin, M. L. Harris, Norman Kerr, J. N. Oswald, Henry G. Anthony, J. W. Class, Hugh T. Patrick, A. M. Hall, George F. Fiske, W. S. Christopher, W. D. Storer, W. W. Quinlan, S. J. Walker, J. P. Houston, and George Chapman. Drs. Frank Billings and Nicholas Senn are the consulting physicians.

Cincinnati Hospital Site Contest.—The Cincinnati Real Estate Exchange has passed a resolution that the city hospital should remain in its present location, at Twelfth and Central avenue, but be put in good and proper condition, in every respect. The Exchange favors the building of a branch hospital on the hilltops.

Endowment of Free Beds.—By the will of the late William McFatrick, of Philadelphia, his residuary estate is after the death of his wife and sister-in-law bequeathed to the Presbyterian, Episcopal, Jewish, Methodist and Howard Hospitals for the endowment of free beds. The widow is requested to donate a sufficient amount to St. Agnes Hospital for the endowment of a free bed.

Post-Graduate Hospital's Needs.—The annual report of the Post-Graduate for 1904 shows that this institution, like most others in the city, is sadly in need of funds. The directors appeal for a contribution of $100,000, which, if secured, will entitle the hospital to $100,000 more which has been promised, provided a similar amount is received from other sources. The home treatment of the tuberculous poor, as carried out by the hospital, has been especially fruitful, as is shown by the fact that more than forty cures of such patients are recorded.

Beth Israel Hospital.—The annual report of this hospital shows a surplus in the treasury, the actual running expenses for the year ending September 30 being $97,449.54, while the receipts were $99,979.08.

Head of Hospital Found Guilty.—The President of the Christian Hospital, Chicago, Dr. N. N. Wood, was held in contempt of court, December 30, for violation of an injunction restraining him from using the name of Dr. John B. Murphy in connection with the hospital. Judge Holdom, in rendering his decision, became very scathing in his remarks, and wound up by fining the Christian Hospital $250, Dr. Wood $100, and ordered him to the County Jail for ten days as punishment.

East Side Physicians' Association of New York.—At the annual meeting of this society, recently held,

the following officers were elected: *President,* Dr. A. Brothers; *Vice-Presidents,* Drs. A. Rose and J. Solow; *Treasurer,* Dr. M. Caspe; *Secretary,* Dr. J. J. Rosenberg.

School Instruction in Tuberculosis.—The Franklin County (N. Y.) Medical Society recently passed a resolution requesting that the State Commissioner of Education urgently consider the advisability of public school instruction in the necessary hygiene for the prevention of tuberculosis. It also voted to submit a copy of the resolutions to the New York State Medical Society, the State Department of Health, and the National Association for the Study and Prevention of Tuberculosis.

The Cocaine Habit in Washington.—Major Richard Sylvester, in his annual report of the police department of Washington, recently submitted to the District Commissioners, calls attention to a bill pending in Congress to regulate the practice of pharmacy and sale of poisons, and urges its passage. The examination of the poison register of one dealer's place alone, he says, disclosed forty sales of cocaine in one day. The drug having been put in properly labeled envelopes, there was no violation of law. Such sales would be retarded very much if cocaine could be furnished only on the certificate of a registered physician and the prescription filled but once, as the proposed law provides.

Russian Red Cross Thievery.—Reports from St. Petersburg state that the Red Cross scandals are receiving a thorough ventilation in the papers, and measures are being taken effectually to put a stop to the wholesale pilfering that went on during the summer and early autumn. One hundred out of 120 bales from Moscow alone disappeared at that time, and since then 125 Red Cross wagons have mysteriously vanished on the way through Siberia. The precautions now taken will it is hoped, effectually prevent a recurrence of the disappearance of supplies, the Emperor having sent a personal aide-de-camp to see that their transportation is not interfered with.

Destitution in Mexico.—It is reported that terrible conditions are existing in the northern part of the State of Sinaloa. Food has been scarce in this region for some time, owing to torrential rains, and in consequence of the latter, malaria has become epidemic. From twenty-five to forty deaths a day are reported from starvation, as well as disease, and the authorities are unable to cope with the situation. In many instances bodies are simply thrown into ditches and canals, without any attempt at burial.

To Secure Brains of Eminent Men.—An attempt is being made to form a society which shall have for its object the education of the public to a realization of the advantages to science attending the study of the brains of illustrious personages. A committee, consisting of Dr. Alexander Hrdlicka, Dr. E. A. Spitzka, and Professor B. G. Wilder, has been appointed for the purpose of preparing a general form of brain bequest, which will hold in law and not be rendered null by any action that may be taken by relatives of the person making the bequest.

Medical Society of the Missouri Valley.—In response to an invitation from the Jackson County Medical Society, the semiannual meeting of the association will be held in Kansas City, Thursday, March 23, 1905. Those desirous of presenting papers should send their titles to the secretary not later than February. Papers will appear upon the programme in the order in which they are received. An invitation has been extended to the presidents of the State associations within the territory embraced by the Missouri Valley, and to the profession in general, and an interesting meeting is expected. The president of the society is Dr. S. Grover Burnett, Kansas City, Mo., and the secretary, Dr. Charles Wood Fassett, St. Joseph, Mo.

A Summer Home for Newark Orphans.—Dr. J. Ackerman Coles of Newark, N. J., has donated a large farmhouse and twenty acres of land near Westfield to the Newark Orphan Asylum Association for use as a summer home for orphans. The gift was made as a memorial to the mother and sister of the donor.

Medical Society of City Hospital Alumni.—At a meeting of this St. Louis society, held December 15, 1904, officers for 1905 were elected as follows: *President,* Dr. John Green, Jr.; *Vice-President, Dr.* Louis H. Behrens; *Secretary,* Dr. R. Emmett Kane; *Treasurer,* Dr. Hudson Talbott.

Chicago Medical Examiners' Association.—The following officers were elected at the annual meeting of the Society, which was held December 19: *President,* Dr. Walter A. Jaquith; *Vice-President,* Dr. Liston H. Montgomery; *Secretary,* Dr. Morton Snow; *Treasurer,* Dr. U. J. Grim; *Councilor of the Chicago Medical Society,* Dr. Walter A. Jaquith.

The November Death Rate in New York.—The report of the New York State Board of Health states that the daily number of deaths in the State during November of this year was greater by fifty-nine, than the average for the past fifteen years. There were 1,220 deaths from pneumonia, 420 more than during October, and 250 more than the average for November. There was also a large increase in the number of deaths from Bright's disease and from cancer.

Obituary Notes.—Dr. Henry Clay Clark died at Woodbury, N. J., on December 27, at the age of seventy-four years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1853. He was assistant surgeon to the Second Regiment, New Jersey Volunteers, during the Civil War, and was taken prisoner at the second battle of Bull Run.

Dr. William C. Haven, President of the Tolland County Medical Association, died at his home in Coventry, Conn., December 26, of pneumonia, at the age of fifty-three years. He was a graduate of the University of New York Medical College in the class of 1877. He had frequently been a fellow of the Connecticut Medical Society, and he had also taken a large interest in public affairs. In 1889 he was a member of the Connecticut House of Representatives, and in 1899 he was a State senator from the Twenty-third District. He leaves a widow and one son.

Dr. William Alexander Ross died at the home of his daughter in Kansas City, Kan., on December 31, at the age of eighty-seven years. He was a grandson of General Alexander Ross, who was a member of George Washington's staff during the American Revolution. Dr. Ross was the first white child born in Boone County, Ky. He had been a resident of Lawrence, Kan., for many years.

Dr. John Greenbank died at Asbury Park, N. J., on December 29, at the age of seventy-five years. He formerly practised medicine in Philadelphia and in New Brunswick, N. J., but retired from active work fifteen years ago.

Dr. Arthur C. Adams, of Washington, D. C., died suddenly on December 31, at the age of fifty-six years. He was a graduate of the Medical Department of Columbia University in the class of 1853.

Dr. Hiram W. Young, of St. Louis, died on December 30, 1904. He was thirty-three years of age, and graduated from the Missouri Medical College (now Medical Department, Washington University) in 1897.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

EDINBURGH UNIVERSITY—ANOTHER TROPICAL EXPEDITION—HOSPITAL APPEALS—PAGET'S DISEASE—ENDARTERITIS—TREATMENT OF INTUSSUSCEPTION—ITEMS—OBITUARY.

LONDON, December 16, 1904.

At the Edinburgh University Court, on Monday, Sir Wm. Turner, as principal, made a most acceptable announcement, viz., that Sir Donald Currie had intimated that he would give £25,000 to be applied by the Court to the remuneration of a staff of lecturers such as the authorities of the university might from time to time think it advisable to appoint. But an option was given to the Court to apply £5,000 of the amount towards the purchase of a site for the new laboratories, if necessary. The Court gratefully accepted the gift and resolved to name the fund after Sir Donald. The principal further announced that in response to the appeal to other friends of the university, he had received and acknowledged intimation of further sums amounting to £15,000.

The thirteenth research expedition of the Liverpool School of Tropical Medicine started on Wednesday for West Africa. On the previous evening, on the invitation of Sir Alfred Jones, about sixty gentlemen assembled to meet the members of the expedition—Prof. Boyce, Dr. Arthur Evans and Dr. H. H. Clarke. The guests included Mr. Walter Long, president of the Local Government Board, who spoke of the unpayable debt they owed to Prof. Boyce, and wondered whether the world-wide extent of the labors of the Liverpool school were appreciated properly, even by those most interested in tropical diseases. Sir A. Jones hoped in a few years the tropics would be made healthy for English people, and with the men around them they could do much more. The American Consul in Liverpool, the Hon. Jas. Boyle, also spoke sympathetically of the work. Prof. Boyce said they who formed the expedition regarded it as a part of their laboratory work, the extension of their observations to other places. Expedition after expedition had been sent out, not only from this country, but from the United States and Germany, but more must follow to remove the prejudice and inertia that prevails by proving the reduction of mortality obtained by their labors.

Hospitals are still making frantic appeals for money to pay off their debts, but none of them seem to make any effort to balance income and expenditure, and most of them continue to dabble in bricks and mortar in a ruinous manner. The treasurer and chairman of Charing Cross Hospital say they are compelled to make a fresh appeal. The bulk of the work of reconstruction is finished, costing £26,399 for the purchase of freeholds, and £115,216 for new buildings, At present £9,000 is still due to the contractors, £3,000 is owing for furniture, and £20,000 is required to accommodate the nursing staff, and adapt the remaining part of the old building. For seven years the institution has been getting deeper and deeper into debt, and with an income of £16,000 average, it is announced that £60,000 must be raised to complete the works, and maintain the charity in working order during the next five years. Does it not seem that the evil system of hospital managers of recklessly running into debt, expecting the public to help them out of their difficulties, is as rampant as ever?

The Royal Surrey County Hospital wants £1,500 to pay off its debt. At a meeting on Saturday the High Sheriff said he would commemorate his year of office by contributing £500, and he hoped his successors would follow the example. Mr. Brodrick urged a determined effort to increase the annual income by £1,000. The present income is £4,200, and the expenditure £5,200. Many other hospitals are in similar straits.

Since Paget described, in 1874, a disease of the mammary areola which has been known by his name, it has been shown that the condition may affect other parts. At the Pathological Society, Mr. A. Hopewell-Smith brought forward a case which he thought showed the disease in the oral tissues. It affected the periphery of an epulis of three years' duration without pain. The specimen looked like a periosteal fibroma with patches of keratohyaline material on the surface. Microscopically there was a tendency towards desquamation of the stratum corneum, and its surface was covered with keratohyaline patches. The cells were ballooned. Some cell-nests, and some myeloid cells were detected here and there. There was some ingrowth of epithelium. Mr. Hopewell-Smith thought the appearance of the neoplasm and the infiltration of the interpapillary processes with small round cells, warranted the diagnosis of Paget's disease. As to the histogenesis of the case, he repudiated Cohnheim's embryonal theory, the mechanical sequestration hypothesis of Ribbert, and the anaplastic one of Hansemann. He thought there was some evidence in favor of the views of Thiersch and Waldeyer, as well as the recent researches of Farmer, Moore, and Walker.

Mr. Shattock considered that Mr. Hopewell-Smith had quite failed to prove his point. The specimens shown as ingrowing epithelium, he said, were only a normal appearance due to the direction of the section. The changes found in Paget's disease were not made out in the present case. Only a small part of a large tumor was examined and described, and it was impossible to form from it a satisfactory diagnosis.

Obliterative endarteritis came up for discussion apropos of a case communicated by Dr. Branson in a boy of 12. All the arteries that could be felt were hard and thickened, and at the post mortem patches of thickened intima were found in the aorta. He had only survived a few weeks after first coming under notice for an overgrowth of the gums, when he was found to have symptoms of granular kidney. He died from uræmia. The kidneys were not granular, but much distorted by deep furrows; the left one about twice the size of the right, the lower half of the latter a mere knot of fibrous tissue. The atrophy seemed to be due to arterial obliteration. Dr. Branson seemed inclined to think the case might have been syphilitic, but he had not been able to trace any evidence of this unless the mother, having had two miscarriages, might be thought so. But surely many women have miscarriages, and this can hardly count in the absence of other indications. Similar cases have been reported among the records of granular kidney in childhood. The marked features being extreme disparity in the size of the kidneys, gross distortion of their outlines and absence of granularity. In these cases the question of syphilis does not seem to have been investigated. In the conversation that followed Dr. H. D. Rolleston thought that all cases of granular kidney in children, except those due to scarlet fever, were syphilitic, or, at any rate, parasyphilitic. Dr. Parkes Weber referred to a form of arterial sclerosis in young Polish Jews, in whom a gradual obliteration of vessels gave rise to gangrene, necessitating amputation. The occlusion was partly arteritis and partly thrombosis. Syphilis was not the cause; many patients had been excessive cigarette smokers. Dr. G. F. Still suggested that the case before the society might possibly have a different explanation. Congenital hydronephrosis might be limited to one kidney. Hypertrophy of the heart would be secondary. Hypertrophy of the gums was usually associated with other congenital deformities.

After all, what is obliterative endarteritis? Dr. Branson noticed the confusion in the use of the term which was introduced by Friedländer in 1876, to describe obliteration of terminal arterioles in inflammatory areas; but was applied by von Winiwarter in 1879 to a lesion of the main arteries of a limb leading to gangrene, and for twenty years some such meaning was attached to it. In 1896 Thoma denied the specific identity of the cases and not much has been recorded of the condition since. Textbook definitions differ. One speaks of it as certainly syphilitic; others admit that no distinction can be shown between specific and nonspecific cases. Others again would call thus any arteritis that produces obliteration. No doubt intimal proliferation plays a part in chronic arterial lesions, however originating. In atheroma the tendency to fatty degeneration is associated in a marked degree; not so in syphilis.

The Treatment of Intussusception in Children was the subject at the Clinical Society's last meeting. Mr. C. S. Wallace read notes of twenty cases; nineteen involved both the small and large gut, the other one was of the colic variety; eleven were single tumors and nine double. The treatment was primary celiotomy, the most convenient incision being through the right rectus beside the umbilicus. He did not lay stress on reduction within the abdomen, thinking time the most important consideration. Deep sutures were rather favored to reduce the danger of the incision coming open from failure of union. Of the twenty cases, four died—twenty per cent. Excluding two cases of resection, the mortality was only 11.11 per cent.

Mr. C. H. Fagge contributed eighteen laparotomies, seventeen primary, one after failure of inflation. In sixteen a tumor was detected either in the abdomen or *per rectum*. The other two cases were fatal; in one no surgeon was called for twenty-four hours, and, though reduction was easy, the child died on the fourth day; the other was of enteric type, irreducible, and was resected. Five irreducible cases were fatal; in one an artificial anus was done; in four, resection. Thus, of eighteen cases, seven died, thirty-nine per cent.; of the reducible cases, thirteen in number, two died, 15.4 per cent.

Mr. Barker was surprised at the number of double cases reported, for he had not met one such in thirty operations. He thought it undesirable for the bowel to escape from the abdomen, as it lengthened the time of the operation and added to the shock; he rarely made an incision above two inches, and had never had the wound open. It was well to do the first dressing under opium and chloroform.

In gangrenous cases he had never seen a recovery after resection and did not expect to see one.

Dr. C. Box spoke of the medical aspect of the subject, and defended the custom of admitting all acute abdominal cases at first under physicians, an extra chloroformization for diagnosis being admissible for doubtful cases. He did not think there was additional shock from escape of intestines, and that was often the greatest aid to the operator. Opening of the wound from non-union he attributed to toxæmia, as in perforated typhoid ulcers after operation.

Dr. Douglas Drew had operated on thirteen cases. Two were gangrenous and died. One was double—the only one he had seen—and the patient died of toxæmia. He reduced within the abdomen, but withdrew the cæcum to examine it. He had not seen the wound burst open.

Dr. Brook had performed inflation with success, but asked whether it was justifiable. He also inquired as to irreducible cases, whether splitting of the outer layer or resection is advisable.

Mr. Wallace, in replying, attributed the number of his double cases to chance, though many might be overlooked in intra-abdominal operations. The length of incision was a personal matter. Some operators could not work with a small opening. Opening of the wound might occur with a one-inch incision; it was certainly due to toxæmia. Inflation should never be done; it was impossible to know if complete reduction had occurred. Disappearance of the tumor might only mean it had slipped behind a flexure or under the liver. He had not heard of successful resection under two years, and manipulation was the only resource. Some force must be used. In some cases, as those of prolapse of ileum through the valve, actual pulling must be tried, as well as pushing or squeezing. He had never seen a recurrence after operation.

Mr. Fagge also replied, agreeing that double cases might be overlooked, but as operation should always be done that was not an important matter. He always made a three-inch incision, even in a small child. He had seen one case of recurrence after operation, but many after inflation.

At an inquest on Saturday, on a girl of eighteen, who died while under nitrous oxide, given for the extraction of a tooth, the immediate cause was said to be cardiac failure. The coroner remarked that the percentage of deaths from the gas was one in a quarter of a million. The present seemed the unfortunate one. The parents testified that every care was taken by the dentist and their doctor, who was also present. Verdict, death from misadventure.

At another inquiry a week ago, concerning the death of a child, caused by playing with fire, the coroner (Dr. Danford Thomas) said that last year inquests were held on 1,684 young children, whose deaths were from burning, and 1,425 of these were because the fires were not guarded.

Dr. Vaudry Lush, physician to the Dorset County Hospital, was seized with cerebral hemorrhage during a meeting of the committee, which he was attending, on the seventh inst., fell from his chair, and died in a few minutes. He was born in 1834, took M.B. Lond. 1865, with three honors; M.D., 1866; F.R.C.S., 1870. In 1879 he joined the College of Physicians as member, and in 1889 its fellowship was given him. He contributed at times to the journals and he had a large practice to conduct, and, besides the county hospital work, he held other appointments, and was most exact in the performance of his duties. His whole career was not merely successful, but he was for many years the leading consultant of a large part of the country and everywhere regarded by the profession and the public as an upright, trustworthy adviser, as well as a philanthropic and Christian gentleman.

ALCOHOL IN THE TROPICS.

To the Editor of the Medical Record:

Sir: I have read with interest Major Woodruff's plea for the dietary use of alcohol in the tropics, as printed in the issue of December 17, 1904. In making mental comment on the article, it has occurred to me to wonder if Major Woodruff has ever thought that it may be entirely within the bounds of possibility to meet all dietary requirements in the tropics, as well as elsewhere, with nutriments that, so far as they are suited to the ordinary needs of life, are sufficiently easy of digestion and absorption, and yet will give all the force necessary through the metabolic processes, and still be well balanced as to their constituent elements, and be devoid of the dangers and disadvantages which always pertain to alcohol when used as a food.

Granting that alcohol oxidizes in the body in certain amounts, and that in extreme conditions it is the only available source of force we can call on, it does not follow that it is desirable to use it as a food in any ordinary conditions. Used in connection with a completely balanced reconstructive nutriment, having a full share of the nitrogen that is indispensable to all vital activities, we all know that for a time, at least, alcohol can be used to improve the nutrition of the body. But when considered in its use as a food, uncombined with such adjunct nutriments, Prof. Atwater, or any one else, is not in a position to prove that the sum total of the complex influences of alcohol is force. There is no known way in which the diverse results of alcohol in the human body can be so estimated as to emphasize or in any case to estimate as to whether the vitalizing or devitalizing influences prevail in dosages of any degree. I have never yet sat out a two-hour dinner in which alcohol had been used in so-called moderation, but what I have not thought that the ultimate influences of its inhibition has been loss of force before the dinner came to an end. The immediate effect of alcohol is agreeable and apparently force-creating; but its anæsthetic, narcotic, and paralyzing influences prevail in the end.

In all discussions of the alcohol question by conservatives, so far as I know, the educational influence of governmental attitude against the use of alcohol as a beverage, never referred to; and yet it is because of the *ultimate* outcome of that attitude that the abolition of the canteen is defensible. What do the lives of a few dissolute, self-unrestrained individuals amount to in comparison with the welfare of the race! One might as well argue that the Japanese were not justified in their individual sacrifices for the good of the nation. We are gradually learning that nutrition for health is best attained by the inhibition of a very simple dietary, and that the exclusion of every unnecessary food is desirable. Alcohol is totally unnecessary under any climatic conditions, though unquestionably a specialized diet for the particular conditions of a tropical climate is necessary. So far as I can see, doctors, as a rule, know but very little in regard to the essentials of diet. How little, for example, is settled in regard to cow's milk and its exhibition to infants and adults. How few hours we all have spent in our college training in the study of this all important subject, and what infinitely weary hours are given to drug exhibitions.

J. M. W. Kitchen, M.D

East Orange, N. J.

THE OPTOMETRY BILL

To the Editor of the Medical Record:

Sir: There appeared in your journal a few weeks ago a letter from Dr. Van Fleet, addressed to the medical profession, which should not be allowed to pass without some notice. The extraordinary statements made by the writer are of such a character that I am reminded of the old saying, that "whom the gods wish to destroy they first make mad." It has always been considered a sure and certain sign of a lost cause when such weapons as misrepresentation are resorted to. Permit me to point out some of the extraordinary statements which he makes. He asserts that "many of the names" of the physicians indorsing the bill "were fictitious," a rather serious charge to bring against the committee of the State Optical Society. Again, he says that "every well-informed physician must know that they (optometrists) are all incompetent." What about the hundreds of physicians of high standing throughout the State who send their patients to optometrists for the reason that they believe that the work will be better done? This is a matter of record and cannot be denied or gainsaid. He says further that we "seek to treat headaches, dizziness, and various reflex phenomena which may be due to affections of organs remote from the eye." How absurd and ridiculous! Our work is simply this, to measure accurately all mechanical defects in the construction of the eye or its controlling muscles and to supply lenses to correct these defects. Should headaches and various other troubles be relieved as a result of our work so much the better for ourselves and the patient. Another astounding statement he makes is to the effect that "to prepare physicians to do this work (optometry) the law requires that a four years' course in a medical college shall be taken, after which a medical examination conducted by the State must be passed." It is difficult to see how any fair-minded man could bring himself to make such a statement, for it is absolutely incorrect. Nowhere does the law require any course, long or short, in medical colleges or elsewhere, or any examination whatsoever by the State to prepare physicians or any one else to do this work (optometry). The field is now open to all comers, from the "well-informed" physician like Dr. Van Fleet, down to the common peddler and street fakir who stands on the corner and sells his glasses to the unsuspecting and unwary.

Our object in seeking legislation on this subject is to prevent incompetents (whether they are found in the ranks of the "well-informed physicians" or elsewhere) from engaging in this work. All should be obliged to undergo a strict and searching examination before a State board,

and those who refuse to do so, and who continue to oppose the enactment of this wise and beneficent measure, should be branded as incompetents. Is it not rather strange that the men who profess to be alone qualified to practise optometry by reason of a four years' course in a medical college have only allotted to them in the study of the eye in all its branches the maximum time of thirty-two hours during the whole four years' course, while those who have given years of study exclusively to optometry are declared by these aspirants to be "all incompetent"? But Dr. Van Fleet's closing statement is certainly the most ludicrous. We are told "opticians know that they are violating the law in following the occupation which they are now engaged in," and "that the enactment of the bill will give them the legal right to do what they are now doing in violation of the law." I would ask, if we are violating the law, why is it that the chairman of the committee on legislation of the medical society is neglecting his duty and does not prosecute us? Perhaps the recollection of the scene before the senate committee in February last still haunts him, when the Optical Society of the State of New York offered to furnish him with the money to prosecute the writer and his associates who practice optometry; but he left the committee room defeated in argument and strategy and forced to resort to other means to defeat the measure which otherwise would have been on the statute books of the State to-day.

Our cause is surely a just one and our purpose honorable. Sooner or later we shall receive recognition and suitable legislation, just as the dentists fought and won their battles against the self-same forces and many of the same arguments as are being used to-day. Who can deny that dentistry is infinitely better done to-day than before the dentistry laws were enacted! So it will be with optometry. The public will then know who are competent to do this work, and fakirs, peddlers, and incompetents will be relegated to the past.

A. MARTIN.

The Relation of the Thymus to Metabolism.—Sinnhuber has conducted a series of investigations on this subject and comes to the following conclusions: The thymus is not an organ important to life in the post-embryonal period. The extirpation of the gland is without influence on the excretion of lime, and the thymus has no causal connection with rachitis in so far as this is concerned with the question of the intake and output of lime. When the gland is atrophied or hypertrophied in this disease neither the rachitis nor the thyroid lesion is either primary or secondary, both are the result of an underlying etiological process. The nature of this underlying process is associated with the lymphatic diathesis and this is usually the result of an interference with intestinal activity caused by insufficient or unsuitable nourishment. In feeding experiments the consumption of thymus gland is without appreciable effect on the excretion of lime, but the nitrogen output is increased. Large doses of throidin markedly increase the excretion of lime as well as the nitrogen output, which is even in excess of the intake.—*Zeitschrift für klinische Medicin*, Vol. 54, Nos. 1 and 2.

An Attempt to Produce a Therapeutically Useful Antibody in Anemia.—Engel, from the results obtained in a case of severe anemia, believes that the improvement was due to the use of a serum injection. Starting with the idea that the primary anemias are due to the effect of some unknown toxic substance circulating in the blood, the author endeavored to produce an antibody in the blood of the rabbit. A considerable amount of blood was abstracted in small quantities at weekly or biweekly intervals from an anemic patient and, after having been made inactive by heating to a temperature of 58° C. for half an hour, was used to immunize a rabbit. The serum obtained from the animal was then used for injection into the patient. The patient's hemoglobin before the treatment was begun was 30 per cent.; eight injections were given in all. After the first injection a considerable reaction was caused, which was less after the succeeding ones. The state of the blood immediately after the last injection is not given, but a year later the hemaglobin was 90 per cent.—*Zeitschrift für klinische Medicin*, Vol. 54, Nos. 1 and 2.

Progress of Medical Science.

The Boston Medical and Surgical Journal, December 29, 1904.

The Ultimate Results of Cauterization of the Lower Turbinate, with Therapeutic Suggestions Based upon Histological Findings.—J. L. Goodale gives a careful description of the histological structure of the nose, showing that the glands of the nose are of two kinds, the mucous and the serous, the distinguishing feature being the presence of secreting capillaries in the latter, and their absence in the former. He then considers the effects of cauterization both beneficial and harmful to the physiological functions of the nose. When the mucous membrane is relaxed, distinct benefit accrues from its contraction. In cases in which intermittent alternating nasal stenosis is due to relaxations or congestions of the tissues, the proper application of a caustic to the lower turbinate anteriorly may be recommended. In cases characterized by excessive secretion of mucus from the posterior nares, with healthy sinuses, but with relaxation of the mucous membrane of the septum, or of the lower turbinates, cauterization meets with improvement in suitable cases. In vasomotor rhinitis of moderate severity, the removal of anterior obstructions often affords marked relief to the symptoms. A caustic application to the relaxed mucous membrane of the lower turbinate anteriorly may be recommended. The most conspicuous alterations from caustic applications are superficial and extend downward in progressively diminishing intensity. The destruction of the ciliated epithelium impairs an important function of the nose, namely, the expulsion by the cilia of the inspired foreign particles from the mucous membrane. The obliteration of the canaliculi in the basement membrane prevents the normal outward flow of fluid intended to moisten the surface of the epithelium. To this may be largely attributed the dryness of the nose and throat of which hay fever patients complain. Another injurious effect of caustic applications is the secondary enlargement of the tissues due to cystic dilatation of the ducts of the glands which may result from stenosis of their orifices. Below the mucous membrane, the alterations consist of a more or less complete obliteration of the blood vessels, lymph channels and glands, with their replacement by connective tissue. Such changes are likely to result in a diminution of the warming power of the mucous membrane. The glandular secretion is also likely to be decreased. As to the method of making these applications, if the object is to contract relaxed mucous membrane, deep linear applications, as narrow as possible, of chromic acid, or of the galvano cautery, or submucous cauterization, offer the best methods. If it is desired to diminish the amount of nasal fluid, broad, superficial applications to a definite area of the septum and lower turbinates, posteriorly, are advantageous. In the event of recurrence of enlargement after cauterization, it is probably best to dispense with further cauterization, and proceed immediately to the excision of a definite amount of obstructive tissue.

Standard Records of the Leucocytes in Normal Blood for Reference in Clinical Work.—Henry F. Hewes has for two years been conducting an investigation upon a considerable number of normal individuals to determine the possibility of finding out the existence or non-existence of leucocytosis, and at the same time of making a differential count to determine the type—the entire determination being made by the examination of a stained specimen alone. He has found that this is feasible and practical. In order to fit himself for the application of this rapid method of blood examination, each man should make a set of records from the examination of specimens of normal blood with his own microscope, thus correcting his own technique, and standardizing his microscope. Thus he will obtain a set of standard normal records for his own use. It must be noted that the number of leucocytes is almost invariably higher in the mid-afternoon than in the mid-forenoon in the same individual. There is in normal conditions no definite variation in the character of the differential count corresponding to a variation in the number of the corpuscles per cubic millimeter, or between the forenoon and afternoon. The table records indicate that this method of computation will bring us within 2,000 of the actual count, which is accurate enough to clinch the diagnosis of the existence or non-existence of a leucocytosis and approximately of its extent. The writer gives the following standard normal rule for use in clinical work: In an estimation of the leucocytes by the method of the count by fields of a stained specimen, the number of leucocytes lies, as a rule, in normal blood during the 12 day hours, between 40 and 90 per 100 fields, the higher numbers occurring regularly in the afternoon. A record exceeding 90 per 100 fields in a good specimen at any time of day is, therefore, suggestive of a leucocytosis. A record of over 80 in a forenoon count is suggestive of leucocytosis, and indicates a further investigation in an afternoon count.

Bacterial Counts of Boston's Milk Supply.—Hibbert Winslow Hill and Francis Henry Slack quote the regulation in regard to the milk supply in Boston, made in April, 1904. It demands that no milk for consumption shall be brought into Boston which contains more than 500,000 bacteria per cubic centimeter, or which has a temperature higher than 50° F. After briefly outlining their laboratory methods for the collection and examination of milk samples, they consider the milk itself, those who deal with it, and the various processes it goes through before reaching the consumer. Boston's milk supply comes from dairy farms situated all over New England. Clean dairymen, clean cattle, clean barns, clean utensils, clean handling and proper cooling are necessary. Reform in these matters can be most readily accomplished through the dealer. The contractor takes more care of the milk which is to be bottled for family trade than of the rest of the supply. If the same care were given to all of the milk as to this, there would be little brought to the city that would not be within the present standard. Mixing the milk is a general custom. It furnishes a fairly standard supply from day to day. The law really forces this as it requires a certain standard of fats and solids. The milk is usually strained as it is poured into the mixer. In summer, millions of flies hover around these mixing rooms and not infrequently fall into the milk. Tasting is necessary to detect poor milk, that is, poor from the standpoint of taste. The methods are varied, and many of them most unhygienic, such as dipping the same spoon into many cans without washing. The writers think that a supply of common wooden tongue depressors would do, carried in a double box, the clean on one side, and the used on the other. A milk kept sweet by cleanliness and cold is much to be preferred to a pasteurized supply filled with lifeless organisms and their by-products. The milk can is responsible for many high counts of bacteria. The unclean can when filled with warm milk affords a lodging place in its inequalities, broken seams, and so on, for the multiplication of bacteria. The cans should be carefully cleansed and sterilized each time they are returned to the farmer. The milk can stopper is generally of wood. It absorbs the milk sooner or later into its pores, and becomes filled with bacteria, and if not properly cleansed with boiling water each time it is used, readily infects the fresh milk. Metal stoppers, which are now used to some extent, offer a great improvement. The outlook for pure milk is favorable. Dairymen are learning the two C's—Cleanliness and Cold.

Medical News, December 31, 1904.

The Effect of Hysterectomy on the Sexual Function.—Hiram N. Vineberg has investigated the histories of a number of patients whose uteri and adnexa he had removed for disease. They all declared that the operation had had no effect upon their sexual passion in any way. He has had patients make the statement that until after the operation they had never known what sexual pleasure was. Others have said that the sexual appetite increased in a marked degree subsequent to operation. In no instance has he been told that the operation destroyed the sexual desire or pleasure. In the investigation of Mandl and Bürger, which included 22 women, in 7 cases there was absolutely no change in the sexual feelings; in 9 cases there was a decrease, and in the remaining 6 cases there had been no sexual intercourse following the operation. Of the 9 women who said there was a decrease several were rather advanced in years, and it was natural that passion had decreased. The writer, from his own experience and from his study of the literature on this subject, concludes that whatever other effects the removal of the uterus and ovaries may have, it has little or no effect upon the sexual feelings.

The Finsen Method.—Milton Franklin concludes that the Finsen method when properly practised—and this necessitates the employment of suitable apparatus free from glass and of sufficient power—is superior to all known procedures for the treatment of lupus vulgaris. The writer has closely observed the results obtained at the only place where the method has been properly employed—at the Finsen Institut. The use of the *x*-ray has been too limited to warrant the positive assertion that it is a specific in lupus. The cases that have been positively cured by the Finsen method are almost without number, while those cured by the *x*-ray are few and scattered, and their authenticity shrouded in uncertainty. The writer states that it may be that we shall finally find a valuable therapeutic agent in the high-frequency currents, but in the meantime we have the ultra-violet treatment of Finsen. He believes that the reason why interest has been lost in the Finsen method outside of Denmark is that the host who have taken it up have been ill prepared to grasp a subject whose accurate understanding requires a knowledge of the physics of optics and electricity. Of the modified lamps, the most important and successful one is that of Piffard. But the results from this apparatus have been almost altogether in cases of lupus erythematosus and other superficial conditions. For this affection, indeed, the results obtained by this form of apparatus are far superior to those obtained by the Finsen lamp. The recent discovery of a new form of radiation in this Piffard lamp may lead to further development along these lines.

Cerebral Palsies in Children.—J. M. Aiken says that the seat of the lesion in the cerebral palsies of children, as in the adult, is in the brain. It is in the central motor neurons, and in that part of the brain that connects the cortex to the spinal anterior horns. The frequency of cerebral as compared to spinal palsies in childhood is about equal. Cerebral palsies in childhood are resultant to prenatal defects, birth accidents, and postnatal causes. The large majority occur during the first three years of life. Prolonged labor is the most common birth accident. From this cause cerebral palsies are more frequent in the case of the younger children of young wives and old husbands. The injuries by accident at birth involve the vessels of the meninges, causing lesions over the motor zone of the cortex. Of the postnatal etiological factors, scarlet fever with nephritis, measles and pneumonia with endocarditis, and embolism and whooping-cough are frequent causes of vascular lesions preceding cerebral palsies. The process, although attacking the motor zone first, is diffuse, and involves intelligence and the special senses. The attack begins with a period of fever and convulsions extending over several days, or even weeks. Motor paresis soon follows, or paralysis involving half of the body, and an upper or lower extremity. Improvement will begin to take place within a few weeks, so that too often an opinion is ventured that the child will outgrow it all. But the cause is chronic and cure is scarcely possible. Mental defect exists in more than 90 per cent of the cases. Soon after the paralysis is established, spasticity of the muscles and exaggerated tendon reflexes develop. Epilepsy develops in one-quarter to one-half of all cases, and athetosis or some purposeless movements are commonly present. It is the physician's duty to inform the parents of the condition of the child in order that money which is needed by other members of the family may not be needlessly spent on the afflicted child.

American Medicine, December 31, 1904.

Ideal Method of Removing the Vermiform Appendix.—Howard A. Kelly describes a plan of removing the vermiform appendix which meets all the required indications and at the same time avoids the dangers often encountered. The base of the appendix is first crushed by a pair of forceps, grooved on the crushing surface and bevelled above, easily managed with one hand and requiring a force of from 30 to 60 pounds in order to lock and to release the blades. The appendix is amputated by means of the ordinary paquelin cautery, after which the base, held by the forceps, is cauterized and sealed by the red-hot point of the cautery, traveling slowly up and down in the groove of the crushing forceps for from 40 to 60 seconds, and, on releasing the forceps, the narrow ribbon of crushed appendix is found converted into a thin translucent tissue with no lumen. The serosa is then united over this by seroserous sutures.

Cause of Death in Operated Cases of Intestinal Perforation Occurring in Typhoid Fever.—Anderson reports his experience in twenty-one cases of laparotomy for perforation. In twelve cases the patients were operated upon under thirty-six hours from the onset of first symptoms with six recoveries. In the remaining nine cases the patients were operated upon from two to four days after perforation and all died. In nine cases there was special treatment by draining or irrigating the lumen of the bowel. Four of these patients recovered. In the others the postoperative symptoms were less severe. Anderson believes that there is a danger of sepsis from the contents of the paralytic bowel, as well as from the peritonitis; that shock as a cause of death is usually rare during typhoid fever; that anesthesia and operations are well borne, if performed carefully; that the peritoneum acquires some immunity to infection during typhoid fever, but that paralytic ileus is readily produced in the inflamed and ulcerated intestine, and the natural protective function of the mucous membrane is destroyed and serious toxemia occurs early; that while perfecting our technic to cure the peritonitis, we must remember the contents of the paralyzed bowel may become a cause of death and must be removed.

Polyneuritis Complicating Typhoid Fever, with Unusual Localizations.—Gordon reports a case in which the nervous phenomena pointed to a multiple neuritis, the associated unilateral facial palsy of peripheral nature making the case unusual from the standpoint of etiology, and leading the writer to suspect possible trouble of a poliomyelitic nature. The case is that of a young man who on the fifteenth day of typhoid fever developed a right brachial monoplegia with a facial palsy on the same side. Gordon analyzes the rôle of infection and intoxications in diseases

of the nervous system and concludes that the toxins of infectious diseases may affect a whole neuron (cell and its axis-cylinder) or several segments of it simultaneously.

Journal of the American Medical Association, December 31, 1904.

The Treatment of Lupus Erythematosus by Repeated Refrigeration with Ethyl Chloride.—Five cases are reported by M. B. Hartzell. The diseased areas should be thoroughly frozen and kept so from five to eight minutes and the treatment should be given every two or three days. Occasionally considerable inflammatory reaction follows, in which case the intervals between freezings should be from four to five days or even longer. After from ten to fourteen days of this treatment considerable desquamation occurs and the diseased areas grow much paler. In the course of six or eight weeks, small and superficial patches of recent origin may completely disappear. In connection with the local treatment large doses of quinine are given internally.

Diseases of Children Occasioned by Affections of the Nose.—L. J. Lautenbach refers particularly to disturbances of the digestive tract, eye and ear. Nasal abnormalities causing obstruction lead to naso-pharyngitis and a dry throat evidenced by a hacking cough, impaired lung action, chest deformities and weak heart action. Then ensue digestive disturbances leading to mal-nutrition with its stomach and intestinal pains, anorexia, cold extremities, bowel inaction, liver congestion, eczema, and boils. At the same time there develops as a result of the nasal obstruction a catarrhal or phlyctenular conjunctivitis with ephiphora, or closure of the ductus ad nasum, or even a keratitis. There usually is an involvement of the eustachian tube, with a loss of hearing power either as the result of direct extension of the nasal inflammation, infection, or closure of the tube, or as the result of pressure alone. In these obstruction cases the memory, the mentality and judgment are more prone to suffer if the posterior nares is considerably involved. The obvious deduction from these facts is not to neglect the ordinary colds of early years, to keep the nasal and pharyngeal channels free and clean, to give such internal remedies as each case calls for and to follow out a carefully regulated hygiene.

Treatment of Chorea by Prolonged Warm Baths.—W. C. Hollopeter emphasizes the virtues of prolonged warm baths in shortening choreic attacks. He finds the baths soothing to the exhausted twitching muscles, productive of sleep and strength-giving. The mode of giving the baths is thus described by the author: The child, when once placed in the bath, is entertained by the nurse or mother by placing some plaything or floating toy in the water, and while the child's attention is so occupied the time will pass rapidly and the attendant's duty will consist in avoiding draughts and in maintaining the temperature of the water sufficiently high (from 90 to 96) so as not to produce any immediate or secondary shock to the child. In this way the child may be entertained for a long time in the water, the whole body being immersed except the head and neck for at least one or two hours, twice a day. The last ten minutes of the time can be properly devoted to a gentle superficial massage of the arms, legs and trunk; after which the child will be sufficiently weary to take a nap. Hollopeter has treated some forty or fifty cases in this way and finds that the duration of the disease is reduced from twelve down to six weeks.

The Resistance of the Peritoneum.—C. M. Echols reports a case of gunshot wound of the abdomen in which laparotomy was not done till seventeen hours after the shooting when the gastrointestinal contents were spread diffusely through the abdomen. The patient was a man of twenty-five years. The author says that with reference to injuries of the peritoneum we should bear in mind (1) that it is by far the most extensive and complicated of the serous membranes; that it is capable of absorbing a large quantity of liquids in a short time; that it can in some patients resist the invasion of large numbers of pyogenic bacteria and withstand considerable handling and trauma with apparent impunity. (2) That a low mortality rate, in any limited series of laparotomies, is not to be construed as demonstrating the operator's superior technic and careful asepsis. The patient's vital resistance may be, and perhaps is, after all, the chief factor in determining whether or not septic peritonitis will follow these operations.

The Lancet, December 17, 1904.

Appendicitis and Pregnancy.—H. A. Lediard and R. E. Sedgwick refer to Pinard's monograph on this subject, published in 1898, in which forty-five cases are collated. Thirty were operated on with a maternal mortality of thirty-three per cent., and a fetal mortality of thirty-six per cent. The authors then report a personal case in which the mother recovered from the operation, but aborted (at the sixth month of pregnancy) four weeks later. Their patient was a married woman of forty years who had borne eight children in nine years and had had one miscarriage. Her symptoms came on in the usual way and she was operated on about a week after their onset. She had had two attacks of "inflammation of the bowels," both occurring in the same part of the abdomen (appendix region) at two previous and separate pregnancies at about the fifth month. Operation was done under chloroform, but healing was slow, as the movements of the child were both seen and felt and obviously did not tend to the formation of a good scar. Healing was not complete until two weeks after the miscarriage. For some days after the operation the wound seemed to get more and more extensive and gaping and omentum was protruded. It was felt that when the wound did heal several unpleasant possibilities might present during labor. The scar, recent and thin, might rupture; a large ventral hernia in all probability would form either during labor, with possible intestinal constriction as a result, or afterwards, in which case a second operation would be necessary for its cure. The risk of procuring miscarriage was thought to be sufficiently great to counterbalance what were after all only reasonable possibilities or probabilities, and nature finally and fortunately came to the rescue and solved all difficulties.

Acute Lymphocythemia.—L. S. Dudgeon reports one case, his patient being a man of 37 years with the usual symptoms. An elaborate table is given of the results of various analyses of the blood. The symptoms during his stay in hospital are summarized in the following statements: There was pyrexia of an irregular remittent type during the whole period of the patient's illness while under observation in the hospital. There was never any very high temperature recorded. There were never any subcutaneous hemorrhages or petechiæ seen. The condition of the mouth gradually became worse and on several occasions the patient had a severe hemorrhage from the gums. Two hemorrhages were seen for the first time four days before he died, in the right disc and retina and one or two dark spots which might have been due to capillary thrombosis. There was never any true glandular enlargement. The urine remained normal during the entire course of the illness. There was never any diarrhea or vomiting. The bones were never tender. The author calls attention in connection with the case to the agglutination of the erythrocytes which occurs in severe anemia, concerning which he thinks no satisfactory explanation has yet been offered, though he thinks it probably takes place in the capillaries. The autopsy revealed large, soft, red succulent glands along the vertebral column downward from the level of the celiac axis; otherwise, the glands were scarcely at all enlarged. The marrow of the ribs was soft and not in excess. It looked like thin, reddish-yellow pus. The femur showed chronic osteitis, the medullary cavity being obliterated, while the outer surface of the bone was rough and irregular. A small quantity of bright yellow fat was obtained from the center of the bone. The lymphocytic infiltration was most marked in both kidneys, though all the organs showed it to some extent.

Operative Treatment of the Conditions of the Gastro-intestinal Tract which Result from Chronic Obstipation.—After an analysis of the various causative factors implied in the title of his paper, W. Arbuthnot Lane states that he has had considerable success from dividing constricting bands and adhesions and from subsequent attention to the functioning of the bowel, but when he finds that the mechanics of the intestines have been altered to a degree that cannot by the divisions of bands be satisfactorily rectified, he divides the ileum some five or six inches from the cecum and then examines the sigmoid flexure and rectum to determine the most readily accessible and safe conduit into which the ileum can be made to drain. In some cases the adhesion of the mesosigmoid and sigmoid flexure is so considerable, and the fixation and wasting of this piece of gut are so great, as to make it advisable to effect a junction with the dilated rectum where the muscle wall is hypertrophied and easily dealt with. In most cases, however, by carefully separating the adhesions it is possible to bring out between the edges of the wound a piece of sigmoid flexure of sufficient length and mobility to effect a perfectly secure and safe junction with the ileum. Having determined on the piece of large bowel which is most suitable for the purpose, the proximal extremity of the ileum is placed alongside the chosen portion and sufficient lengths of each are secured together by suitable forceps, gauze packing being placed about. Longitudinal incisions are made in the approximated pieces of bowel and by means of a continuous silk suture penetrating all the coats, the aperture of communication, which should be of sufficient length, is rendered perfectly secure. To avoid any possible risk this junction is supplemented by an encircling continuous silk suture which does not enter the lumen but obtains a secure hold upon the peritoneum and muscle coats.

British Medical Journal, December 17, 1904.

The Germ-Cell Theory of Cancer.—Albert S. Grünbaum refers first to the morphological continuity of the germ-cells, which he explains briefly as follows: After the union of the sperm and the egg, there is formed by the subdivision of the united cell what corresponds to a larva, or trophoblast; in man the chorion. From one of its cells there is formed, as it were, a number of spores. One of these spores ultimately becomes the embryo, which includes within itself the remaining spores to become its sexual cells, which are thus not formed from the embryo, but are handed down to it, and for which it merely forms a home. It has been suggested that the aberrant germ-cell might be the origin of a cancerous growth. As to the connection between the germ-cell and a malignant growth, it has been found that there is in malignant tumors a form of nuclear division which normally occurs only in the sexual cells, amongst the spermatozoa and ova. One of the distinguishing characteristics of this heterotype mitosis is the formation by the dividing cells of only half the normal number of chromosomes. The other characteristics were also observed in the cells of malignant growths. These discoveries show that there must be something in common between the germ-cell and the tumor-cell. This form of nuclear division has not been found in innocent tumors. The writer believes that the distinction between innocent and malignant tumors is not fundamental. The heterotype mitosis does not occur at once in the evolution of the sexual cells. It may not occur at first in tumors, and in this stage they are not malignant, but when this supervenes, they become malignant. The writer declares that given the cell or cells of the potential growth, it seems not improbable that the toxin of a parasite, the short stimulus of a trauma, the long-continued stimulus of chronic irritation, or the chemical conditions of disordered metabolism, might be sufficient to call forth their energies into activity, and thus one or all of the alleged causes in turn might have their share.

Death Under Nitrous Oxide.—John G. Owen believes that owing to the rarity of deaths under the administration of nitrous oxide, it is desirable to record every case. The patient, whose history he reports, was a cretin, aged 18, of keen and well-educated intellect. She was barely three feet tall, and almost unable to move about. She had taken gas well before, and no trouble was anticipated. She took it well this time and went under quickly, but became more cyanosed than usual. Only one tooth was extracted and the patient appeared to be coming around, when there was a slight convulsive movement of the hands and limbs and breathing ceased. Efforts at restoration, although persisted in for an hour, failed to revive the patient. Post-mortem examination showed an extremely thick skull cap and an apparently normal brain and membranes. The larynx and air-passages were clear; no trace of the thyroid could be seen, but there was a large, persistent thymus; the weight of the heart was seven ounces, apparently not disproportionate to the size of the patient; the mitral valves were thickened and incompetent, but the ventricles were not hypertrophied. No other lesions were found.

Diabetes After Operation.—Mark R. Taylor operated on a strong, healthy laborer, about 30 years of age, for strangulated hernia. The wound healed by first intention. There was troublesome retention of the urine for ten days, but otherwise the convalescence was uneventful. About two months later, a crop of boils developed on the patient's arm, due to a poisoned scratch on his finger. These soon disappeared. In less than three months he complained of frequency of micturition and intense thirst. He had noticed these symptoms but three days. The urine was loaded with sugar. Two days later he was admitted to the hospital, and died in five days, just five months after the operation.

Warning Signs of Danger During Labor.—W. Macfie Campbell refers to the paper on this subject by Daniell, and reports a case of his own. The patient was a multipara, aged 36 years, whose former labors had been rapid and uneventful. In the present instance, although labor had proceeded for four hours, no progress was made. Chloroform was given and the pains at once became stronger and more regular, but the head did not advance. The axis traction forceps was applied, and shortly after there was a curious movement of the handles—they were retracted twice with a backward movement. Delivery was accomplished as quickly as possible, with regard to the mother's safety. The child was stillborn. The cord was once around the neck, with the short end to the placenta, the folds crossing, so that the fetal end of the cord was quite bloodless. The writer believes that this forceps movement is due to the fact that the infant suddenly deprived of placental blood, tries hard to breathe and dies suffocated. He gives these points of warning: First the retraction of the presentation like a ball on a rubber cord; then, if the neck could be reached, freedom to the compression could be given; and, secondly, the movement of the forceps, but when this is felt, the end is very near, and only forced delivery, with disregard of consequences to the mother, would give any chance of a living child.

Treatment of Hemoptysis.—H. Hyslop-Thomson describes this treatment as follows: As soon as hemorrhage begins, the head and shoulders should be raised, and a hypodermic injection of morphine given, the dose varying from 1-6 to 1-3 of a grain. Thirty to forty grains of calcium chloride dissolved in a little water should be injected high into the rectum, and an icebag applied to that part of the chest immediately underlying which is the most active tuberculous focus. Heat should be applied in order that blood may be drawn to the lower limbs. The value of morphine in hemorrhage depends upon its power of stimulating the inhibitory center, by means of which the cardiac action is slowed. As to the value of the administration of calcium chloride, it may be said that active fibrin ferment is rich in calcium, and wherever coagulation takes place, calcium in some form or other is present; and the conditions which favor coagulation in the lungs are feeble, for blood, after circulating several times through the pulmonary vessels without being allowed to enter the systemic circulation, loses its power of clotting.

Deutsche medizinische Wochenschrift, December 15, 1904.

Anesthetization by the High Pressure Method.—Engelken describes a plan of procedure intended to make thoracic operations possible without the dangers attending pneumothorax produced under ordinary conditions. Sauerbruch's method consists in the use of a pneumatic cabinet designed to contain the operating table, together with the surgeon and necessary assistants, etc., while the head of the patient passes into the outer air through a hole in the side of the cabinet. On exhausting the air in the cabinet to the necessary degree, collapse of the lung on opening the pleural cavities is avoided. The author has reversed this plan and rendered the performance of operations of this sort much simpler by having the patient's head and the anesthetizer enclosed in a smaller cabinet in which the atmospheric pressure is raised above the normal. The details of construction, including the highly ingenious system of valves necessary, are described as well as the necessary provision for aspirating all free chloroform vapor, in order that the anesthetist may not suffer from its effect himself. A pulmonary tumor has already been removed by means of this cabinet, which was found satisfactory in its operation.

The Necessity for Perforation of the Living Child.—Baisch does not agree with those authorities who believe the living child should never be sacrificed, and that the necessity for doing so never arises. He is of the opinion that under some conditions perforation of the child, even though living, is the most conservative procedure, and he describes the five cases in which he was impelled to resort to the measure. If there is any suspicion of infection, sympheseotomy or conservative cesarean section are contraindicated, and to remove the uterus of a young woman who may be so far without living children is unjustifiable. The proper course in such cases is sacrifice of the child in order to bring the mother safely through the crisis, and then at a subsequent pregnancy to perform conservative cesarean section in a hospital under the necessary precautions. In one of the author's cases, a living child was in this way secured at a pregnancy following a previous perforation. The author believes that Gigli's operation of hebotomy is a very promising addition to the resources of the obstetrician, and will probably be found in proper cases, to be the most suitable of the major obstetric operations for private practice.

Etiology of Erythema Nodosum.—Hoffmann says that the attempts that have been made to include this infection in the category of erythema multiforme are ill-advised as there are numerous characteristics of form, localization, tendency to recurrence, and epidemiology which make it clear that we are dealing with two distinct affections. Still, what is usually described as erythema multiforme is not a simple quantity, for the poisons of various infectious diseases and different drugs, such as iodides and bromides, may cause a typical eruption. The author accordingly makes three classes of the disease, (1) idiopathic erythema multiforme, (2) the symptomatic form, and (3) the toxic form. The etiology of the latter two types is, of course, not so obscure, but the causation of the idiopathic form is unexplained. Several observations on microscopic sections of the cutaneous swellings, lead the author to believe that the disease is due to a localized phlebitis of sub-cutaneous veins due to the invasion of the blood stream by a staphylococcus, which probably enters the body through the tonsils. Various considerations concerning the structure and functions of the veins of the lower extremities are pointed out which favor the localization of bacterial growths in this situation, and, therefore, account for the fact that the tibial surfaces are the sites of election for the lesions of erythema nodosum.

Annals of Surgery, December, 1904.

Morphology of Carcinoma and the Parasitic Theory of Its Etiology.—Prof. J. Orth concludes that up to the present time no one has produced proof that carcinoma is of parasitic origin, and that there is no need to assume a parasitic origin of the disease. The great characteristic of cancer cells is that they are none other than epithelial cells, not only in accordance with their structure, nature of protoplasm and nuclei and biological activities, but also in accordance with their origin. One kind of epithelium may become transformed into another, but a connective tissue cell can never be transformed into an epithelial cell. The stroma of a cancer is without any significance for its organization. There can be cancerous growth without any stroma, though the latter may determine the variety or character of the growth. Every cancer is an epithelioma, but in order to differentiate it from other epithelial growths, it may be designated as aberrant epithelioma, the distinction being that in cancer, epithelial cells are found in localities where epithelium does not normally exist. The arrangement of cells may be typical or atypical, with many mixed or transitional forms. The foregoing being true, it is not possible for a parasite to be the chief etiological factor. An intra-cellular parasite may play a part in the process but it is impossible for it to play an independent part, and it cannot be the decisive factor in the new growth. It is a matter for consequence etiologically to prove the transplantability of cancer, to produce a secondary cancer even upon another individual; but it is of consequence to produce a primary tumor. As long as that is not successfully accomplished, and that by means of an organism in pure culture, so long is also the parasitic nature of cancer not proved.

Some Experiments with a New Method of Closing Wounds of the Larger Arteries.—G. E. Brewer relates his experience with an elastic plaster for meeting the indication named in the title of his paper. The ideals of such a plaster should be thinness and a capability of maintaining its elasticity for several days after being imbedded in the tissues. It must be very adhesive, and capable of complete sterilization. The material, finally selected was zinc oxide plaster on thin strips of pure rubber, and formaldehyde vapor was employed as the sterilizing agent. The author then details his experiments on animals. As soon as the artery is exposed, it is brought to the surface of the wound and incised with the point of the scalpel. The vessel is then compressed above and below the wound, to prevent excessive hemorrhage, and the sheath carefully removed. The artery is next cleansed of all blood by the use of a small pledget of gauze moistened with ether. As the ether evaporates, the vessel wall is left clean and dry. A small strip of the plaster is next passed beneath the vessel, and the two corners held by two small artery clamps in the hands of an assistant. The strip is then put gently on the stretch and the lower extremity of the strip held by the clamps placed firmly in contact with the vessel, while the upper extremity of the plaster is slowly drawn upward. This causes the vessel to rotate with the plaster until the horizontal edge of the lower extremity of the plaster is on a level with the vessel and firmly adherent to it. The two clamps are then passed over the vessel, and the plaster kept on the stretch while the operator, with his thumb and forefinger, gently rotates the vessel backward, and at the same time compresses the enveloping plaster until it adheres snugly. The redundant plaster is then removed and the vessel allowed to fall back to its normal position in the wound. No opportunity has yet offered of trying this method on the human subject, but the success attained on dogs has been such as to lead him to believe that the plan is fully worthy of trial.

Parotitis Following Injury or Disease of the Abdominal and Pelvic Viscera.—B. Dyball reviews the studies previously made on this complication by various men. He notes that three theories have been put forward, first, the pyemic, second, that of oral sepsis, and third, the reflex. None of these satisfactorily explain all cases. He sums up by saying: (1) It appears most probable that cedematous parotitis is due to the action on the parotid glands of toxic substances absorbed into the blood and derived from (*a*) the secretions of certain organs modified by injury or disease; (*b*) toxins of microbic origin (*e. g.* bacillus coli) absorbed either from the alimentary canal, peritoneal cavity, or bladder; (*c*) products of deranged digestion. (2) In any given case of injury or disease of the abdominal or pelvic viscera, the occurrence or not of parotitis will therefore depend on the presence and the absorption in sufficient quantity of some of these various toxic agents. (3) Suppuration is not an essential feature of the condition, but is due to the fact that the parotid gland, when inflamed by the action of these toxic agents, forms a *locus minoris resistentiæ*, and becomes secondarily infected by pyogenic organisms reaching it (*a*) by the blood-stream; (*b*) by Stenson's duct.

Duodenal Ulcer.—W. J. Mayo reviews the clinical aspects of fifty-eight operated cases, and adds some remarks on gastrojejunostomy. His cases are divided into the following groups: First—acute perforation, six cases, two deaths; second, hemorrhage, one fatal case; third, chronic duodenal ulcer, with gastric complications, twenty-eight cases, one death; fourth, chronic perforating ulcer, with gall-bladder and liver complications, eleven cases, one re-operation, no deaths; fifth, chronic ulcer requiring operation for relief of pain and distress, thirteen cases, no death. Mayo notes that at the present time posterior gastroenterostomy would appear to be the operation of choice in chronic cases, but grants that the last word has not yet been said. It is pretty certain that even with a large gastroenterostomy food will pass out by preference through a patent pylorus by muscular action, the apparent gravity advantage of a low-point gastroenterostomy being equalized by intra-abdominal tension. Closure of the pylorus to divert all the food to the artificial outlet is under consideration by the author, and he thinks it should be done in the large majority of cases if there is no cicatricial obstruction.

Tetany and Foreign Bodies in the Stomach.—J. P. Warbasse reports a remarkable case of this nature, a mass being removed by gastrotomy, which was composed of forty metallic articles weighing in the aggregate one pound. Cure resulted. The patient was a young man of twenty-three years, who gave exhibitions of swallowing small metallic objects. He never swallowed many at one time, and generally found them in the dejections within twenty-four hours. He suffered at times from severe colic, cramps in the legs and back, occasional choking sensations and difficulty of breathing, due apparently to spasms of the throat muscles. Finally, on one occasion he fell in a tetanic attack and was taken to hospital. The fluoroscope detected a mass of foreign matter in the cardiac end of the stomach. The following articles were removed by the gastrotomy: Seven pocket-knives, seven door-keys, twenty nails (two and one-half inches long), one small spoon, one button-hook, an ordinary pin, a knife-spring, and two watch-chains (one gold-plated, the other silver). The total weight of these things was sixteen ounces. The mucous membrane of the stomach appeared slightly congested, but otherwise normal. The musculature was apparently not hypertrophied. There were no peritoneal adhesions or evidences of irritation, excepting the adhesion of the stomach to the former scar. The patient afterward recognized one knife he had swallowed five months before, and the buttonhook had been swallowed ten months before. The copper parts of the knives were not bright, but dull in appearance, and there were no gross evidences of the presence of the chloride of copper. Nor did the patient present any symptoms of poisoning from copper salts. His appetite was always good.

Hernia of the Bladder Complicating Inguinal Hernia.—Four cases are reported by F. J. Shepherd, who states that the commonest form of bladder hernia is the extraperitoneal in which the bladder protrudes toward the lower and inner part of the sac, the posterior and inner wall of the bladder forming the lower and anterior wall of the sac containing the bowel. In most cases the sac containing the bowel protrudes beyond the bladder, but its lower wall is continuous, with the peritoneum covering the posterior wall of the bladder. The latter may be altogether within the sac, the intraperitoneal portion alone protruding, or there may be hernia of both portions. In all the author's cases it was the extraperitoneal portion which protruded, and the lower wall of the hernial sac was bounded by the bladder, the peritoneum forming this part of the sac being closely attached to the bladder, and pulling that organ down as it protruded. From the author's experience he would caution surgeons to bear in mind the following points: (1) The inguinal opening is always large, out of proportion to the size of the protruding intestines. (2) The cord is not intimately associated with the sac of the tumor, but can be readily held aside without dissection; it is usually to the outer side of the tumor. (3) In two at least of his cases the hernia was a direct one, and in all had been produced by a sudden strain. (4) The difficulty of finding a neck to the sac, for the anterior portion of the sac stretches away toward the pubis, and is perhaps covered with granular and very vascular fat. In his fourth case the condition was complicated by the presence of a collection of fluid in front of the sac, which extended into the scrotum.

The American Journal of the Medical Sciences, December, 1904.

Intermittent Hyperchlorhydria as an Occasional Cause of Recurrent Vomiting in Children.—Irving M. Snow believes that recurrent vomiting of children is not as rare as is generally supposed; that it is relatively easy of diagnosis, an examination of the vomited matter being most

important; that at least in some cases the gastric irritability is due to an intermittent hyperchlorhydria, a secondary neurosis, causing the sudden hypersecretion of free HCl and gastric juice. The disease, as a rule, begins in early childhood, from the first to the sixth year. The writer's patients all belonged to the better class of society and were nervous, high-strung children of average physique. None of them had been weakened by any exhausting illness. The greatest care was used in regard to their feeding. The prodromal symptoms were of no consequence—languor and slight fever. Many of the attacks occurred with no warning, beginning suddenly, with no adequate cause, ending abruptly, leaving the digestion undamaged, with weeks or months of excellent health. Of 20 recorded cases, 12 of the patients were girls and 8 were boys. The vomiting attacks occur at irregular intervals. In four of the writer's cases the fluid vomited was apparently pure gastric juice, containing an excess of free HCl and mucus, and in the fifth case the hyperacidity was due to combined chlorides. The writer believes that the cause of this disease is still unknown, but it is probably a transitory autointoxication, playing with full force on the nervous centers governing gastric secretion and motion, and in some cases the gastric lesion is an intermittent form of hyperchlorhydria. Although nearly all cases recover, it is noted, as knowledge of the disease becomes more general, that an increasing number of fatalities are reported. The post-mortem findings are necrotic changes in the gastric and intestinal mucosa and inflammatory or irritative lesions of the kidney. The alkaline treatment was most successful in at least one of the author's cases, and should always be tried. In dangerous conditions nutrient enemata, chloral by rectum, and hypodermics of morphine and strychnine may serve to tide over a dangerous crisis.

Medical Treatment of Gastric Ulcer.—Samuel W. Lambert declares that the two cardinal points in every ulcer cure and regimen are rest and milk diet. Rest is perhaps the more important of the two. These patients should be kept in bed until the characteristic pain and tenderness consequent upon the taking of a mild but varied diet shall no longer appear. The rest cure in these cases does not mean such an absolute isolation as is indicated for the more serious forms of neurasthenia. It is sufficient that the patients stay in bed and give up all business cares and worries. They may receive short visits and play games and read. Daily alcohol spongings and baths, and mild forms of massage to the arms, legs and back, will improve their general condition. This rest cure will rarely need to be prolonged beyond six weeks. As soon as this cure is begun a period of absolute abstention from food by the stomach should be inaugurated. Nothing but water and pieces of ice should be swallowed. Nutrient enemata are of great assistance in keeping up the strength of the patient. In the morning the patient is given a high lavage of the colon, with four quarts of saline solution. After an hour the enemata are begun and may be continued at intervals of four hours during the day. Each enema may consist of egg, milk, or meat-broths, or of combinations not exceeding 4 ounces in bulk. All such foods should be predigested to a degree of complete peptonization, by means of pancreatic extracts and bicarbonate of sodium. The rectal feeding should be omitted during the night. Gastric feeding may be resumed in mild cases within four days, but in the severer cases it will be necessary to wait a week or more. The problem to secure a milk which will not irritate is the same as that which has been solved for the artificial feeding of infants—that is, to diminish the proteid and still keep the sugar and fat percentages the same as in normal cows' milk. All hard food must be omitted from the regimen, as well as condiments, spiced and highly cooked sauces and condiments, and even an excess of common salt. Overfatigue must be avoided even after the patient has returned to work. The writer concludes his paper with the consideration of the treatment of special symptoms and complications.

The Surgical Treatment of Gastric Ulcer.—Joseph A. Blake believes that the treatment of acute gastric ulcer is essentially medical, yet the exacerbations of a chronic ulcer are probably not infrequently mistaken for an acute ulcer, and the cure is consequently not permanent. Unless operated upon 98 per cent. of cases of perforation die. The most important advance has been the establishment of the fact that early operation is absolutely necessary for the attainment of good results. Obstruction from cicatricial contraction occurs most often at the pylorus, more rarely at other parts, where it gives rise to hour-glass contraction. Pyloric and hour-glass obstructions can be helped by surgical intervention only. This treatment gives most excellent results, the mortality, unless the patient is nearly moribund, being about 5 per cent. In the cases of uncomplicated pyloric obstruction Finney's operation is very successful, while in cases of stenosis due to ulcer, gastroenterostomy with or without pylorectomy appears to be the operation of choice. Hemorrhage in this trouble is a serious complication. The writer believes that a single large hemorrhage, without previous symptoms referable to ulcer, should not be operated upon, but when there have been antecedent symptoms operation should be at once performed. Excision of the ulcer, combined with gastroenterostomy, is the method of choice. In the treatment of chronic ulcer surgical treatment has the advantage. The majority of symptoms causing ulcers are situated in the pyloric region, and are consequently at a point where the utmost benefits are derived from gastroenterostomy. If possible, excision of ulcers in the cardiac portion of the stomach should be practised. The writer makes a plea for earlier resort to surgical measures, not only in ulcer but in malignant disease.

Some Unsettled and Important Problems in the Treatment of Acute Lobar Pneumonia.—Beverley Robinson emphasizes the following points: Judicious, rational treatment should be begun immediately and be continued during the attack. The most useful single agent in treatment, as preventive and curative, is creosote, used preferably by inhalation, properly given and continued for a sufficient length of time. There should be strict avoidance of extremes of treatment in any direction, whether it be toward the use of so-called specifics or the employment of certain drugs, notably digitalis and strychnine. It should be graven on the physician's mind that pneumonia may be throttled or minimized most surely in the beginning. Later, when the disease is fully developed, our rôle is inferior, but should consist mainly in doing least harm. Harm proceeds almost invariably from ignorance or undue enthusiasm.

On the Presence of Organic Acid in the Urine in Cases of Rheumatoid Arthritis.—Helen Baldwin, after very careful work on this subject, presents the following conclusions: In the graver forms of acid intoxication, as in diabetes and certain forms of mania, the acid excretion is in so large quantities that there is marked increase in the ammonia excretion to neutralize this acid. In the cases of rheumatoid arthritis, however, the percentage of ammonia is not increased, so as to be an indication of a condition of acidosis. The normal percentage of the nitrogen of ammonia is from 2 to 5 per cent. of the total nitrogen. The average in the specimens examined was 5.4 per cent. In all of these cases of rheumatoid arthritis, with progressive lesions, there are certain definite evidences in the urine of perverted metabolism. In only three cases were the stomach contents examined, and in all of these there was an absence of free hydrochloric acid after a test meal, although the patients had no other symptoms of gastric indigestion. Intestinal putrefaction was found to be constantly excessive in those patients who had active symptoms of the disease. Besides these evidences of gastric and intestinal disorder there was regularly found in the urine organic acid other than normally present. As the various forms of organic acid are readily oxidized in the body, the amount formed is probably in excess of the amount excreted. Patients leading as inactive lives as those with rheumatoid arthritis would naturally be subject to gastrointestinal indigestion, but the regularity with which such symptoms are noted and their degree would suggest that certain of the disturbances of nutrition which occur in rheumatoid arthritis are due to these putrefactive processes in the intestine.

The Diagnostic Value of Leucocytosis.—G. W. McCaskey believes that the following conclusions are warranted: A routine enumeration of the white cells in the peripheral blood is of sufficient importance to be made a regular procedure so far as possible in all cases. A single leucocyte count is entirely insufficient as a basis of conclusion in any given case, and should be followed up by several made under different conditions. An increase beyond 10,000 or 12,000 leucocytes in the peripheral blood indicates varying grades of intoxication, which chemotactic substances of some sort or another. Whether it indicates suppuration or not is a question to be determined by carefully weighing all the facts in each case. The leucocytes indicating suppurative and allied processes are of the neutrophile type. The eosinophile form of leucocytosis indicates, among other things, and perhaps principally, cutaneous or parasitical diseases in the intestine or elsewhere. Lymphocytosis clinically signifies an irritative lesion of the lymphatic apparatus. A differential count should be made in all cases to determine the type of cell which has been the subject of the principal increase where such increase exists, and such records carefully kept and collated as a basis for the determination of the clinical significance of leucocytosis in the future. In the diagnosis of malignant disease a leucocytosis is of very subordinate value, and when present is probably not due to the malignant disease, per se, but to coexisting chemotactic toxins.

Book Reviews.

HANDBOOK OF THE ANATOMY AND DISEASES OF THE EYE AND EAR. For Students and Practitioners. By D. B. St. JOHN ROOSA, M.D., LL.D., Professor of Diseases of the Eye and Ear in the New York Post-graduate Medical School; formerly President of the New York Academy of Medicine, etc., and A. EDWARD DAVIS, A.M., M.D., Professor of Diseases of the Eye in the New York Post-graduate Medical School; Fellow of the New York Academy of Medicine. Philadelphia: F. A. Davis Company, 904.

NONE can realize better the need that has long existed for a brief and complete compend on the eye and ear for either undergraduate or postgraduate work than they who are constantly teaching in these branches. As a rule, a beginner can in no wise digest or assimilate the larger works of reference on these special subjects and greatly added responsibility for that reason is given the teacher. Again, as the majority of pupils usually take up the study of both eye and ear at about the same time, the authors' combination of the two subjects under one cover is practical. After grasping the principles of the anatomy and diseases of the eyes and ear, as presented in this book, the student can intelligently consult larger treatises. Stress is wisely laid on the etymology of the nomenclature and the index is well arranged, full, and easy of reference. The general practitioner, as well as the student, will find this a useful addition to his working medical library.

A TEXTBOOK OF HISTOLOGY. Including Microscopic Technic. By A. A. BÖHM, M.D., and M. von DAVIDOFF, M.D., of the Anatomical Institute in Munich. Edited, with Extensive Additions to both Text and Illustrations, by G. CARL HUBER, M.D., Professor of Histology and Embryology, and Director of the Histological Laboratory in the University of Michigan. Second Edition. Thoroughly revised and enlarged. Philadelphia, New York, London: W. B. Saunders & Company, 1904.

IN revising the text of the first edition of this work the American editor has taken the opportunity of including the results of many of the important recent researches in this field. Especial attention has been given to the illustration of the structure of glands and other elements by means of reconstructions in wax by the method of Born, which hitherto has been chiefly used in embryology. Serial sections are made first, and these are drawn with the aid of a camera lucida. The drawings are traced on wax plates of uniform size, and the wax tracings are cut out. The different wax models of the serial sections are superimposed in proper sequence, and thus the organ is reconstructed. In this way many features which cannot be illustrated in microscopical sections are brought out. The text has been enlarged in this edition by some forty pages, and to make up for this the bibliography has been omitted. This must have been done at the last minute, however, as the text bristles with names of authorities followed by reference numerals, which mean nothing in the absence of a bibliographical index. The omission of this index is to be deplored, and it is to be hoped that it will be restored in future editions.

CLINICAL DIAGNOSTIC BACTERIOLOGY, including Serum Diagnosis and Cytodiagnosis. By ALFRED C. COLES, M.D., D.Sc., F.R.S., Edin. With two colored plates. London: J. & A. Churchill; Philadelphia: P. Blakiston's Son & Co., 1904.

THE object of this work is to give a concise and practical guide to clinical diagnostic bacteriology to practitioners who have not had the training of the laboratory, nor possess the equipment for such work, but who desire to avail themselves of the aid of bacteriology in diagnosis. The author presents, therefore, those methods which are most useful in practical diagnosis, and describes those germs which are usually looked for in clinical work.

Special attention is naturally paid to the tubercle bacillus, the gonococcus, the diphtheria bacillus, the pneumococcus, and the germs of pus formation. The latest methods that have proved useful are given as a rule—as, for example, the methods of Wahl and of Poppenheim in staining gonococci. The parasitic fungi of the skin, etc., are given a brief chapter, and the subjects of cytodiagnosis and serum diagnosis are considered in a sufficiently detailed manner for practical purposes. A number of chapters are devoted to the consideration of acid-fast bacteria other than the tubercle bacillus, and perhaps this subject has received such prominence owing to the fact that the author has published various researches on this question. While this subject is of great importance, the practical and elementary nature of this book does not require that 76 pages out of 237 should be devoted to it. We think, therefore, that in this detailed consideration the author has overstepped his self-set goal.

STRABISMUS, OR SQUINT, LATENT OR FIXED. A Supplement to the Errors of Refraction. By FRANCIS VALK, M.D., Professor of Diseases of the Eye, New York Post-Graduate School and Hospital; Consulting Ophthalmologist, Thrall Hospital; and formerly Assistant Surgeon, Manhattan Eye and Ear Hospital; Visiting Opthalmologist, Randall's Island Hospitals, and Ophthalmologist to the New York Dispensary; Fellow of the New York Academy of Medicine and of the State and County Medical Society; Member of the Greater New York Medical Society and the Society of Medical Jurisprudence, etc. New York and London: G. P. Putnam's Sons, 1904.

THIS work presents the views of the writer on heterophoria and heterotropia, gained by an experience of a number of years, and these views are expressed freely, qnite irrespective of the views of other writers on this subject. In the first chapter, which is entitled "Argument," and in the chapter on "Movements of the Eye," the author's position is somewhat vaguely set forth. A proper revision of these chapters would much improve them. An effort has been made to substantiate the author's belief that tests by means of prisms and by means of the tropometer are the only reliable ones for the determination of heterophoria; that the fusion sense should not be disturbed in making tests of the extrinsic muscles of the eye, and that because of this the so-called "disassociation tests," by means of the Maddox rod, screen, etc., are faulty and objectionable. Reference is made to a "fusion center" and a "fixation center," which exist as yet in theory only and might better be written of as faculties until such centers are demonstrated anatomically.

Separate chapters are devoted to the consideration of exophoria, esophoria, hyperphoria, heterophoria, and heterotropia. The writer rejects the theory of Donders regarding the development of heterophoria and heterotropia, substituting principally the theory of congenital excess or insufficiency in the power of the ocular muscles.

In the chapter on "Strabismus, Concomitant or Functional," the writer has endeavored to construct a theory of strabismus which shall meet all cases. Operative procedures devised and developed by the author are advocated, and these are fully described. The work is one that should be read by those who are interested in this particular field, because it presents views that may well be considered.

A MANUAL OF EXPERIMENTAL PHYSIOLOGY for Students of Medicine. By WINFIELD S. HALL, Ph.D., M.D. (Leipsic), Professor of Physiology, Northwestern University Medical School; Professor of Physiology, Wesley Hospital School for Nurses, etc. With 89 illustrations and a colored plate. Philadelphia and New York: Lea Brothers & Company, 1904.

THIS is a well-planned laboratory handbook comprising a series of exercises in experimental physiology, to be carried out by undergraduate students. The author's choice of the work to be done is most satisfactory and bears evidence of seasoned experience as a teacher, as does also the introductory chapter, telling how the book should be used. The entire province of general physiology is covered and appropriate exercises are grouped under the headings of cytology, the general physiology of muscle and nerve tissue, the circulation of the blood, respiration, normal hæmatology, digestion and absorption, vision, the nervous system and the muscular system. An appendix gives various convenient formulæ and directions for the construction and care of apparatus. The material is all presented in practical, easily intelligible form and the book is well designed to meet the needs of teachers and students. The section on hæmatology alone is not on a par with the excellence of the rest of the book and is unsatisfactory in some respects. For example, among the methods of determining the hæmoglobin neither that most accurate intrument, the Miescher modification of Fleischl's hæmometer, nor the very practical Sahli hæmometer, is mentioned. The simple and universally applicable Jenner stain is not included among the blood stains described, and cells with basophilic granulations are not spoken of either in the description of the normal leucocytes or in that of the cells of the bone marrow. The one colored plate in the book is devoted to the morphology of the blood, but is drawn from specimens prepared with Ehrlich's stain, which for general work is fast being supplanted, in this country at least, by the newer combinations of eosin and methylene blue, and this plate, of course, gives no hint to the student of the existence of the basophilic granulations. Also most of the specimens depicted are taken from pathological blood and so hardly fall under the chapter heading of normal hæmatology. A much more useful plate would be one showing the development of the cellular elements of the blood in the fœtus and in bone marrow or showing something of comparative hæmotology. However, the whole subject is one that is preferably taught outside of the physiological laboratory and the present volume is more than good enough in other respects to compensate for its shortcomings in this section.

Society Reports.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Fourteenth Annual Meeting, Held in Milwaukee, Wisconsin, December 28 and 29, 1904.

The Association met in the Colonial Hall of the Plankinton Hotel, under the Presidency of Dr. CHARLES H. MAYO of Rochester, Minnesota.

Kidney Stone.—Dr. A. L. WRIGHT of Carroll Iowa, read a paper on this subject, in which he presented the following conclusions: "(1) Kidney stone may occur at any time of life, from the earliest to ripe old age. (2) These stones are the most frequent, and give rise to the greatest amount of suffering of any form of surgical disease of the kidney. The clinical manifestations of kidney stone do not depend upon its size. A small stone, just large enough to prevent its escape, and composed of oxalate of lime, will cause more suffering and damage to the kidney parenchyma than a very much larger deposit of softer formation, as well as completely disable the patient while the destructive changes are taking place, although the clinical symptoms are not intensely active. (3) While generally unilateral, stone occasionally occurs in both kidneys, or the reflex symptoms may point most prominently to the sound kidney, the stone being found not infrequently on the side free from pain. (4) Diagnosis is not difficult in the typical cases, but owing to the stone remaining quiescent in some for an indefinite period, recognition may be almost impossible. (5) Owing to the fact that kidney stone may put on the livery of infectious diseases, the diagnosis is difficult, if not impossible, in those cases where the classical symptoms are absent. (6) There are few diseases of the kidney more certainly fatal, when left to themselves, yet more successfully treated when encountered by proper surgical interference, arresting the destructive changes taking place in the kidney, and restoring the viscus to its physiological functions."

Dr. ALEXANDER HUGH FERGUSON said that this branch of surgery was by no means complete from an etiological and diagnostic standpoint, nor from the viewpoint of treatment. Pain was sometimes very deceptive. It was both local and referred; local in the region of the kidney itself, and referred to different parts of the body, chiefly along the genito-urinary tract from the testicle, sometimes toward the midline of the abdomen, at other times toward the ensiform cartilage in the region of the gall-bladder and duodenum, and not infrequently it was referred to the back. Pain was caused in nearly all cases at first, when there was no septic urine, by stretching of the pelvis of the kidney and of the kidney tissue, the calices, etc., this stretching causing excruciating pain. A quiescent stone did not always cause colic, although it frequently gave rise to referred pain. In the diagnosis one should consider tumor of the kidney, recurrent attacks of interstitial nephritis, and tuberculosis of the kidney. The *x*-ray was one of the best aids to diagnosis at our command. He called attention to the dangers incident to the passage of such instruments as the segregator, cystoscope, etc. He reported a case illustrating the difficulty in making the diagnosis.

Dr. W. D. HAINES, when acting as Coroner's Physician, had made over two thousand autopsies, and in about 50 per cent. of the cases he found stones of variable sizes in the kidney. In many of the cases it was impossible to trace the history, but in a number of them, in bringing out the forensic aspect, he was able to trace the history accurately. In those cases in which the history could be traced, it was surprising to find how infrequently symptoms were complained of referable to the kidney. In treating these cases surgically one of the principal things to determine was the presence of a kidney on the opposite side. An instructive case was cited.

Dr. WRIGHT, in closing, maintained in regard to the cause of pain that it was inflammatory in character, and not due, as claimed in textbooks and by teachers, to stretching of the kidney tissue. Many of these kidneys were opened, where the clinical manifestations indicated the existence of stone, but none was found except possibly a little débris, possibly nothing. Furthermore, where the deposit consisted of oxalate of lime the pain was very excruciating. The stone was too large to engage in the ureter, but not large enough, however, to stretch the pelvis or parenchyma of the kidney, or to produce any stretching effect whatever, so that he believed the same would apply to the presence of stone in the kidney, as in gall-bladder work, in which pain was not due to the passage of gall-stones, but was of an inflammatory character, and that when such kidneys were opened and drained, and no stone or stones found, relief was prompt.

Newer Aids to Diagnosis in Diseases of the Urinary Tract.—Dr. M. L. HARRIS of Chicago in a paper with this title, arranged the newer aids to diagnosis in diseases of the urinary tract in the following order, according to their value: (1) the cystoscope; (2) ureteral catheterization or segregation, with comparative analyses of the separate urines; (3) the *x*-ray; (4) the phloridizin test; (5) comparative cryoscopy of the separate urines; (6) cryoscopy of the blood, with the necessary corrections made.

Dr. B. B. DAVIS had been using the Harris segregator a great deal in making tests as to the relative condition of the two kidneys, and asked whether the essayist had observed temporary anuria in any of the cases, enough to interfere materially with the value of the test. Dr. Davis then related a recent case in which there was temporary anuria following the use of the segregator.

Dr. HARRIS had observed temporary anuria, which lasted sometimes a few minutes, sometimes ten or fifteen minutes. He had noticed it in a number of instances. He had seen it last as long as thirty or forty minutes, but how long it would have lasted had the examination been continued he did not know. Temporary anuria, however, was not common. It was exceptional. He had also seen temporary anuria follow the introduction of the ureteral catheter, which lasted for several hours, or until the catheter was withdrawn.

Methods of Exploring the Abdomen, and a New One.—Dr. ALEXANDER HUGH FERGUSON of Chicago stated that in the daily round of work the surgeon met cases requiring colpotomy, anterior or posterior, to remove myomata or cysts, and these cases often gave a history of stomach, gall-bladder, kidney, or bowel disturbances. An examination of the abdominal organs was highly satisfactory, although oftentimes one felt hardly justified in opening through the abdominal wall for that purpose. The problem was solved by passing the hand and entire forearm into the abdominal cavity through the vagina. In order to furnish enough space for this purpose, it was imperative to cut through the mucous membrane of the vagina its whole length on each side post-laterally. The mucous membrane being severed, the other structures would stretch at once. The bare arm being smeared over with sterile vaseline, glided in with ease. He had within the last three years, both in private practice and at his clinics, passed his hand through the vagina to the diaphragm, and palpated all the abdominal organs. In one case, after detecting gall-stones, he cut down upon the gall-bladder and pushed it, full of biliary calculi, through a buttonhole incision in the abdominal wall. In another case a cancer of the rectum was present, and before removing it it was indicated to learn the condition of the internal organs. He passed his hand and detected cancer of the liver and gall-bladder. Still a third case, a maiden lady of mature years, had a vaginal outlet so small that a digital examination could not be made without an anesthetic. He then found cancer of the posterior lip of the cervix. Through an anterior colpotomy he passed his hand, after having slit the vagina on each side, and found the anterior surface of the stomach involved with a firm hard tumor, evidently cancerous, and

the lymphatics were also extensively enlarged with the same dreadful disease.

Dr. R. C. Coffee asked under what circumstances the essayist would make such an exploration as he had described, inasmuch as the vagina could not be thoroughly sterilized, and an abdominal incision was fraught with so little danger?

Dr. A. L. Wright spoke disparagingly of this method of exploration, although he had never tried it. He questioned the possibility of being able to render the vagina aseptic. The mortality was so slight from an abdominal incision and the dangers attending it so small, that the method of Dr. Ferguson impressed him as being much more formidable and attended with more danger than an abdominal incision.

Dr. C. O. Thienhaus called attention to the method employed by Ott, who introduces an electric light through the vagina into the abdomen, at the same time using one on his forehead, with which he can explore the abdominal cavity, and see diseases with the eye which could not possibly be diagnosed otherwise, and dealt with accordingly.

Peritoneal Adhesions, Their Cause and Prevention.—Dr. Arthur E. Hertzler of Kansas City, Missouri, stated that he had studied peritoneal adhesions by means of a small glass window sewed into the lateral abdominal wall of an animal. Peritoneal surfaces might agglutinate without a destruction of the endothelial layer. In true adhesions the endothelial layers were always destroyed. If the basement membrane was not destroyed, the adhesions might separate after a time. If the basement membrane was destroyed, the union was formed by a true growth of fibrous tissue, and was permanent. Ordinary adhesions were formed by fibrin formation, with a loosening of the cement substance of the basement membrane, and an interlacing of the fibers forming the basement layer. This formed in twelve to eighteen hours. The formation of peritoneal adhesions depended on the same factors as blood coagulation. The irritation of the surface destroyed the endothelium, permitting the escape of fibrinogen-forming fluid. The Ca Cl is abundant below, and immediately below the endothelial cells, as may be demonstrated by silver nitrate. The escape of the leucocytes from the vessels which attended every irritative process activated the proferment, and made it active. The precipitate of fibrin thus formed was identical with that form in blood coagulation, as might be demonstrated by microchemical tests. The identity was further demonstrated by the fact that those factors which prevented coagulation also prevented peritoneal adhesions. The methods most employed were phosphorus and peptone. The former prevented it by destroying the fibrinogen, the latter by acting on an antiferment. The presence of a digestive ferment in the upper intestinal tract explains why adhesions formed less readily in spontaneous perforations in this region.

Operation for Undescended Testicle. Dr. Emerson M. Sutton of Peoria, Illinois, reported the case of a boy, eleven years of age, a cryptorchid, who suffered from strabismus and nervousness, but otherwise was well. In making an incision in the inguinal canal the testicle was found above the internal ring free; the cord was retained by a band extending posteriorly toward the median line, and upward opposite the second lumbar vertebra. Blunt dissection was resorted to until the cord was freed and the testicle deposited easily in the bottom of the scrotum without tension. The retaining step of the operation consisted in a buttonhole incision through the bottom of the scrotal sac posterior to its middle, where the skin was less elastic, catgut stitches inserted through the edges of the skin and albuginea, or testicle, in a way which held the end of the testicle attached to the skin, necessitating healing by granulation. The convalescence was uncomplicated, and the testicle was permanently fixed in the bottom of the scrotum and was of natural size. He stated that many operations for this affection had been planned, as Kocher's circular stitch, sewing the cord in the canal without strangulating it; also Watson-Cheyne's retaining stitch through the bottom of the scrotal sac and then the testicle, tied to the under wire of a retaining frame, to be moved after three weeks, when the organ had become fixed in place by adhesions. Objections to attaching the testicle to the bottom of a movable sac were valid, since experience demonstrated the futility of such a method. The Katzenstein operation of making a flap from the inner side of the thigh was a step in the right direction. However, with the modifications employed in the author's case, considering the satisfactory results, the surgeon could fix the testicle absolutely.

Dr. Sutton also reported a case of aneurysm of the superior mesenteric artery upon which he had operated.

The Practical Significance of Certain Common Symptoms in the Upper Abdomen.—Dr. J. F. Percy of Galesburg, Illinois, read a paper with this title. These symptoms were pain from ulcer of the stomach and cholecystitis, with or without stones, and the action of the gastric juice on an open ulcer either in the stomach or duodenum. Another source of pain was the formation of gas from inhibited peristalsis, due to ulcer or adhesions arising from it. Vomiting was also referred to as one of the symptoms of disease in this region, but in the author's experience it was not as frequent as nausea. Two methods were referred to as an aid to the location of lesions in the upper abdomen, one being light finger percussion eliciting pain over the inflammatory focus, in patients not too obese, and the resistance of the costal cartilages on the right side in inflammatory conditions of the gall-bladder and in ulcer of the duodenum or pylorus, as recently pointed out anew by Elliott. The author laid special stress on the effects of chronic infections of the liver and pancreas from ulcer of the stomach and persistent cholecystitis, and cited cases in point. He stated that some of these cases were rarely diagnosed correctly. Biliousness and dyspepsia were the words most frequently used as descriptive of the diagnosis and upon which the treatment was based. The author stated further that a persistent infection would in an appreciable number of cases cause death regardless of the form of treatment which might be instituted, because of alteration in the functionating tissues of the liver and pancreas. Future investigation would show that the results of this infection were chemical through the intervention of bacteria at work in ulcerating areas in the stomach, duodenum or gall-bladder.

Dr. John B. Murphy congratulated the essayist on bringing out with greater force the fact that a differential diagnosis between lesions of the pyloric area of the stomach, the head of the pancreas, and the gall-bladder was extremely difficult. He was pleased that the essayist brought out the periodicity of exacerbations in ulcers of the stomach. A large number of cases of ulcer of the stomach had pronounced exacerbations. They were practically well in the period between the attacks. Dr. Murphy detailed an interesting case corroborating the latter statement.

Dr. Alexander Hugh Ferguson stated that when a pain came on suddenly, which was referable to the epigastric region, although no tenderness could be elicited in that region, but could be over the gall-bladder, it tended to show that the seat of the trouble was within the gall-bladder, the stone or stones being engaged in the cystic duct. Pain occurring while the patient was in a quiescent state, or occurring after the patient went to sleep, pointed to the gall-bladder rather than to any other organ. A lancinating pain, only coming on occasionally and referable to the region of the gall-bladder and ducts, pointed to carcinoma. Pain referred to the region of the ducts was more characteristic of gall-stones. In cases of stone or tumor of the kidney, as well as in tumor of the suprarenal capsule, pain was generally referred to the back. Pott's disease should not be overlooked. Pain referred to the testicle and radiating into the genito-urinary tract pointed towards the

kidney as the seat of the trouble. Still, pain was referred sometimes to these regions from other conditions than stone in the kidney.

Dr. William D. Haggard said that while expertness and refinement in diagnosis were desiderata, surgeons must realize that many of the cases under discussion were not amenable to the niceties and refinement of diagnosis to which attention had been drawn. In reference to differences in pains and colics of which patients complained, he referred to the importance of a well-taken clinical history, saying that a great deal of dependence should be placed on it.

Dr. B. B. Davis had been struggling for years against the habit of making incisions without having made a careful and sufficient study of the case beforehand, but he had concluded that a man was more dangerous who did not make such incisions occasionally than the one who did make them before he had made accurate diagnoses. He related a case which he thought to be one of cholelithiasis from the symptoms and clinical history, yet much to his surprise in operating he found a large appendix, turned up underneath the gall-bladder, with dense adhesions around the cystic duct. There were no stones found in the gall-bladder; it was perfectly patulous, and after freeing the adhesions he could squeeze bile out without any trouble. He did nothing to the gall-bladder, simply removed the appendix, and thus far relief had been complete.

Splenic Anemia.—Dr. Palmer Findley of Chicago reported a case of splenic anemia in which he removed the spleen with good results. The patient was forty-five years old, had suffered for four years from a dragging sensation in the left side and uterine hemorrhage. Blood examination showed reds, 2,784,000 per cubic millimeter; leucocytes, 6,000, and hemoglobin, 42 per cent. Thirteen months after operation her blood showed reds, 4,600,000; leucocytes, 6,000, and hemoglobin, 78 per cent. In spite of the fact that the uterine hemorrhage continued, the patient refused curettage for its control. Dr. Findley offered a word of caution in the hasty diagnosis of splenic anemia without giving due consideration to other possible causes for splenic enlargement associated with a secondary anemia, such as malaria and syphilis, and advised splenectomy for only the rapidly progressive cases, reserving medical treatment for the milder form.

High Frequency Electricity in the Treatment of Surgical and Gynecological Diseases.—Dr. E. M. Sala of Rock Island, Illinois, related his personal experience with the d'Arsonval high frequency current, and reported several cases comprising a variety of affections in which the immediate results were gratifying, but what the permanent results were going to be, he could not predict. However, he was convinced that the d'Arsonval-Odin apparatus had a very promising future.

The Care of the Axilla After Excavations for Malignant or Infective Lesions.—Dr. John B. Murphy of Chicago discussed this subject, saying that extensive dissection of the axilla was not infrequently followed by contracting painful cicatrices, limitation of motion, edema, neuralgia, etc. These can be relieved or avoided by (a) line of skin incision; (b) immediate grafting or transplantation; (c) muscular implantation, and (d) muscular conservation.

Moorhof's Bone Plug.—Dr. James E. Moore of Minneapolis, Minn., read a paper on this subject. The author stated that in January, 1903, von Mosetig reported a large number of successful results from the use of a new bone plug. This material consisted of sixty parts iodoform, forty parts spermaceti, and 40 parts of oleum sesami. These ingredients were slowly heated to 100° C., and when allowed to cool formed a soft solid, which remained solid at the temperature of the body. For use it was heated to 50° C., being constantly stirred to keep the iodoform evenly distributed. At this temperature it could be poured into the cavity, where it immediately solidified. The material did not act as a foreign body, nor did it act as a culture medium. It possessed the inhibitory and medicinal properties of iodoform without causing iodoform intoxication. His experience with this material, although limited, was sufficient to satisfy him that better results could be obtained in treating bone cavities than by any older method, and in illustration of this he reported four recent successful cases.

Dr. Arthur T. Mann stated that last winter he saw Moorhof use his bone plug. The first case in which he used it was one of tuberculosis of the tarsal bones of the foot, with a discharging sinus on the side. Moorhof made an incision across the full front of the ankle, catching up the tendons with sutures to be tied later, cut the tendons, turned the foot down, removed the astragalus, a third of the os calcis, and curetted away some tuberculous tissue, cut out the skin and tissue about the sinus, put the foot in its position, drew the sutures on the tendons, tied them, and filled the bone cavity with this bone plug. Moorhof told him that he expected the plug to fill in with bone. He also showed the speaker a series of *x*-ray pictures taken of a similar case a number of months before, in which the result was eminently satisfactory. He mentioned other cases Moorhof had treated by bone plug with satisfactory results.

Dr. Moore, in closing, said that cases could now be treated successfully with this bone plug in which formerly amputation was done, as, for instance, in cases of tuberculosis of the wrist and ankle joints.

Extirpation of the Gasserian Ganglion in the Treatment of Facial Neuralgia.—Dr. A. E. Halstead of Chicago stated that during the last decade the treatment of inveterate facial neuralgia had progressed mostly along surgical lines. The injection of osmic acid into the peripheral branches of the nerve, either directly through the overlying tissue or after exposing the nerve by incision, first proposed and practised by Neuber, and lately revived and extolled by Murphy, had its physiological counterpart in neurotomy. Probably regeneration was somewhat longer delayed after its use than after simple section of the nerve, owing to its property of hardening nerve tissue, but in the end regeneration, with return of function, undoubtedly occurred. After speaking of the different methods and technique of extirpating the ganglion, Dr. Halstead reported seven cases, in which he had extirpated the ganglion for the relief of facial neuralgia. From the cases the author reviewed and from his own experience, it seemed possible to have a return of the pain after the removal of the ganglion. Nevertheless, he believed with Cushing that "the probability of non-recurrence bore a direct relation to the degree of entirety with which the ganglion had been removed." In his own cases he had each ganglion subjected to a careful examination by a competent microscopist. In all of the specimens submitted ganglionic elements were found, and the gross anatomical characteristics of the organ were preserved.

Dr. John B. Murphy stated that in his 12 cases of removal of the Gasserian ganglion, there were 4 deaths. This large percentage of deaths caused him to abandon the operation. Since his last report he had had one recurrence of neuralgia from the injection of osmic acid. In the entire number up to date, with this exception, he had not had a recurrence thus far.

Mortality, Disability, and Permanency of Cure in Surgery.—This was the title of the President's address, which was delivered by Dr. Charles H. Mayo of Rochester, Minnesota. The author stated that a careful selection of cases, asepsis, and the kindness of Providence might give a low death rate which would cover much poor surgery. There was no general rule for computing surgical mortality at present, and it was best to accept the layman's view that the operation had caused death where the patient went into the hospital alive and came out dead, regardless of the cause of death or time after operation. Failure to grasp the surgical opportunity at the proper moment was the cause of an increased mortality and disability, as well as a reduction in cures. The layman as well as the professional

man understood that many diseases, such as appendicitis, ulcer of the stomach, and gall-stone disease, might each have repeated medical cures, and that in the same cases early operation was successful with a low mortality, the complications of delay causing the most trouble. During this year in St. Mary's Hospital 516 operations for appendicitis were made, with 4 deaths. Their hospital detention was reduced an average of eleven days each, amounting to fourteen years' saving over the time which would have been required for the same work five years ago. In 205 hernias during the year this saving was from one to two weeks in each case. Among stomach operations, 108 gastroenterostomies gave 8 deaths (7.4 per cent), most of these in late cancer, while 13 pylorectomies and partial gastrectomies gave no deaths because in an early stage. There were 5 deaths in 101 hysterectomies, more than one-half of these being due to an increased effort to cure cancer. Altogether, up to December 1, 1904, 1,000 operations for gall-stone disease gave a mortality of 5 per cent. There were 673 cholecystostomies, with 2.4 per cent. mortality; 186 cholesystectomies gave a mortality of 4.3 per cent.; the common duct cases, 11 per cent.; cancer, 22 per cent, showing that one case in 5 had passed the safe time for operation, while early operation in 416 cases gave but 2 deaths. The brain was poorly constructed for repair, hence late operations gave only occasional permanent and complete cures. The progress in the treatment of cancer was through a study of lymphatics involved in metastasis.

(*To be continued.*)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held December 15, 1904.

DR. ANDREW H. SMITH IN THE CHAIR.

THIS meeting was held under the auspices of the Section on Genito-Urinary Diseases, and the subject for discussion was that of "The Diagnosis of the Surgical Lesions of the Kidney and Ureter."

The Objective and Subjective Symptoms of Renal Lesions.—Dr. CHARLES L. GIBSON read this paper. After considering the chief symptoms of surgical diseases of the kidney he offered the following, which were in brief the chief diagnostic factors of the important surgical lesions of the kidney in their order of importance: *Abnormal mobility*—History; recognition of displacement by examination; associated neurasthenia and gastroenteroptosis; direct and indirect pain. *Tumors*—Age; sarcoma in infancy, carcinoma in later life; cachexia; tumor; pain, hematuria. *Congenital polycystic kidney*—Large kidney-shaped tumor, irregular surface, sooner or later bilateral; chronic diffuse nephritis; pain and discomfort from dragging and pressure; occasional hematuria. *Hydronephrosis unilateral*—Antecedent history of blocking of one ureter, usually by a calculus; large, painless, rounded, fluctuating tumor in the loin; absence of constitutional and uremic symptoms; compensatory hypertrophy of the other kidney. *Hydronephrosis, double*—History usually of chronic obstruction to the escape of urine from the bladder, or of malignant growth pressing on both ureters; recognition of the source of obstruction. *Pyonephrosis*—Antecedent history of infection and obstruction; large globular and fixed tumor in the flank; if process was acute, febrile and other constitutional symptoms. *Pyelonephritis or surgical kidney*—Usually history of long obstruction, plus infection; mostly elderly men with obstructing prostate and men in middle life with stricture; recognition of the obstruction and cystitis; a low grade chronic sepsis; occasional acute exacerbations with chills and febrile disturbances; chronic diffuse nephritis; seldom any enlargement or tenderness of the kidney; usually bilateral. *Tuberculosis*—History of constitutional tuberculosis; other tuberculous foci, especially of the genito-urinary tract; persistent evening rise of temperature; very insidious and latent course of symptoms; polyuria from chronic diffuse nephritis; frequency of urination, even in earlier stages before marked changes in bladder; irregular hematuria without apparent cause; pus thoroughly mixed with urine of an acid reaction. *Renal calculus*—The passage of sand, gravel, or small calculi; typical renal colic; attacks of hematuria, especially if accompanying renal colic; symptoms of suppuration in the kidney; local pain and pyuria; recognition of an enlarged kidney due to pyelitis or hydronephrosis; excess of crystalline sediment; temporary oliguria followed by polyuria; gouty or rheumatic diathesis and chiefly in middle-aged individuals.

Laboratory Findings in Surgical Diseases of the Kidney.—Dr. FREDERICK E. SONDERN said that the clinician with proper laboratory training in exact chemical technique was best fitted for performing scientific as well as practical urinary analysis, but in practice this ideal was impossible because the clinician had not the time at his disposal, and the laboratory expert required such an array of delicate apparatus in perfect adjustment, and carefully standardized reagents, that the average clinician could not afford to maintain them unless the work occupied his entire time. The relation between the clinician and the laboratory expert ought to be like the ideal association of the physician and surgeon. As to the quantity of urine, he thought twenty-four hour specimens taught many significant points not learned in any other way. In considering the significance of a polyuria, that due to neurosis, diuretics, ordered intake of much fluid, a previously removed kidney, or an occlusion of one ureter should not be forgotten. In oliguria that due to unilateral painful lesions, reflex, or without obstruction, must be kept in mind. Owing to the omission of a test for glucose, because the specific gravity created no suspicion, a post-operative diabetic coma had often come as a surprise. The usual tests for glucose were made much more sensitive by keeping the tubes in a warm water bath in preference to simply boiling. Pentosuria was by no means the uncommon condition formerly believed. Many cases of pentosuria were called glycosuria because a differential test was not made. In testing for albumin the methods should be such that nucleoalbumin, albumose, and Bence Jones albumin were not overlooked or confused. Concentrated urines showed faint traces of albumin much more clearly if they were diluted with water before testing. He considered that the normal amount of urine excreted in twenty-four hours was from 16 to 28 grammes. The relative and absolute excretion of chlorides had renewed attention of late; the method by incineration must be advocated, and the direct method condemned. The great value of the centrifuge had been established, and the statement that renal elements were destroyed or structures formed that simulated casts had been disproven. The microspectroscope demonstrated the proper bands from one red blood cell. The presence of a granular cast did not necessarily indicate a chronic nephritis, nor did a nephritis demand the constant presence of casts. Tumor particles were sometimes found in the urine, and justified a conclusion; but a diagnosis of carcinoma or sarcoma of the kidney, based on the presence of a cancer cell, was simply absurd. Methods for determining the functional ability of the kidneys had proven decidedly useful, though not infallible. Molecular concentration, determined by cryoscopy of the blood, was perhaps the best procedure. Cryoscopy of the urine applied to any given specimen, or to a twenty-four hour specimen, taught little or nothing. Previous intake of large amounts of fluid was not advisable if this test was to be used. Electric conductivity of the urine taught nothing in addition to cryoscopy. The phloridzin, methelene blue, indigo, and carmine tests had not gained the popularity here that they had abroad, and their value seemed to decrease from year to year. In acute catarrh of the renal pelvis, if due to a local cause, calculus or pronounced crystalline deposit, the daily amount of urine was decreased, there was corresponding concentration, normal output of solids, blood cells according to local irritation, few leucocytes, some mucus, characteristic groups of epithelial cells, and albumin or

casts, according to the degree of hyperemia of the parenchyma. In the event of an ascending infection, the urine showing the evidences of a bladder lesion, suddenly became scanty, with some increase in the albumin, and the presence of few casts, and epithelial cells referable to the pelvis, but with the normal daily output of solids. In either case the acute catarrh disappeared or the picture became that of pyelitis. In pyelitis with hyperemia of the parenchyma, the daily amount of urine was increased, the gravity lowered, and the microscopical picture showed pus in addition to the element found with catarrh of the pelvis. In pyelonephritis the same features were present as in pyelitis, with the addition of albumin and casts. Purulent exudates from the kidney did not form a coagulum as frequently as those from the bladder, and were always poorer in epithelial cells. Renal hematuria, unless the bleeding was very profuse, also lacked the tendency to coagulation. In hydronephrosis and pyonephrosis, with occlusion of the ureter, the urine might be normal, but usually showed polyuria, and slight hyperemia of the parenchyma. The microscopical picture obtained when a pyonephrosis was discharging into the bladder was quite meager, but the necrotic character of the pus assisted in the diagnosis. Aspirated fluid from a hydronephrosis or pyonephrosis was very easily identified. Urine analysis presented little of value in the specific diagnosis of cysts of the kidney. In renal actinomycosis the urinary picture was that of pyelitis with hyperemia of the parenchyma, or of pyelonephritis with more or less frequent hematuria. In malignant tumors intermittent hematuria was the most frequent abnormal feature in the urine. The presence of blood detected on microscopical examination between the attacks of pronounced hematuria was a very suggestive feature. In renal tuberculosis the picture at first was that of pyelitis with hyperemia of the parenchyma, an almost invariable presence of a few blood sells, and a distinct polyuria; later there were evidences of pyelonephritis. Finding the bacilli in the sediment had been much facilitated by the centrifuge, and success in finding them was largely due to patience and painstaking search. There were cases of renal tuberculosis in which the bacilli could not be found, and in such cases animal inoculation was often, though not invariably, successful. Tuberculous urine usually had an acid reaction. In the event of animal inoculation the presence of the tubercle bacillus should be demonstrated microscopically. While the differentiation of tubercle bacilli and smegma bacilli was not difficult by the use of standard methods, where there was a marked alkaline fermentation, tubercle bacilli did not withstand the action of alcohol as well. An opinion based on the presence of single bacilli must remain guarded. The diagnosis of tuberculous and renal disease could usually be made from the urine, and success was due to patient examination of a number of specimens. In cases of renal calculus the urinary picture was most varied. The urine might vary from normal to that characteristic of pyelonephritis and cystitis. From his experience he had come to regard the relatively high nitrogenous output as an important point in differential diagnosis. The differential point between intermittent hydronephrosis and stone colic, was that in the former the amount of urine was usually large, and the gravity low, while in the latter the opposite was the rule. In nephralgia and allied conditions, the urinary findings might so closely resemble those of other diseases that a differential diagnosis was usually difficult, and at times impossible. Careful and repeated analysis, while it might not lead to positive results, was of value in excluding other conditions. In contemplated kidney surgery in diabetes, the surgeon should be more influenced by the evidences of intoxication than by the percentage of glucose. A routine blood examination taught much of value in forming an opinion as to the necessity and urgency of operation in septic kidney lesions. He thought that the differential count of leucocytes offered a reliable guide as to the status of the inflammatory process. He closed his remarks with the dictum: "The man who makes every diagnosis in the laboratory is as short-sighted and liable to grave error as the man who ignores microscope and test tube."

The X-Ray.—Dr. Lewis Gregory Cole said that his paper was supplementary to a former one. Until recently the *x*-ray was used only as a possible aid in diagnosing renal and ureteral calculi. Within the last year or so there had been improvements in the apparatus and technique which enabled us to make skiagraphs of moderate-sized subjects, on which the diagnosis might be made regardless of signs and symptoms. By diagnosis he meant the negative as well as positive diagnosis of calculi. In order to do this the ray of selective absorption must be obtained. This was sometimes difficult to accomplish. It was possible to show some renal calculi in skiagraphs made without this ray, but such plates were worthless in making negative diagnoses. He referred to the necessity for short exposures, on account of the motion of the kidney during respiration, and because of the danger of burning the patient, and said there was also another danger, *i.e.* fogging the plate by the rays that went around the patient instead of through him. For all patients weighing 150 lbs, or less, his rule was from 5 to 15 or 20 seconds for the exposures. With the recent improvements finer gradations of shadows and greater contrast between the different soft tissues were shown. As these shadows increased the difficulty of reading or interpreting the plates increased. Many of these shadows could be misinterpreted as renal or ureteral calculi. Near the lower end of the ureter there were shadows cast which very closely resembled ureteral calculi both in size and location. In speaking of the range of positions of the renal calculi, he said that in all cases he had the tube 18 inches from the plate, vertically over the umbilicus, and showed that the variety of the positions of the stones was astonishing. In order to make a negative diagnosis, the spine and transverse process of the lumbar vertebra must show distinctly clear-cut edges all the way to the rib. The last rib and psoas muscles must also show, but the kidney and wall of the intestine were not really necessary for even a negative diagnosis.

The Cystoscope and Ureteral Catheter.—Dr. F. Tilden Brown outlined the uses of these instruments in diagnosing renal diseases. He said that no other agent had done so much to advance the work in this field as the cystoscope and ureter catheter. He first spoke of the importance attaching to the cystoscopic pictures of the ureter mouth in the diagnosis of affections of the upper tracts. He described the appearance of ureteral mouths which might be considered normal, while at the same time severe kidney disease might exist. He also spoke of the mouths that impressed us at once as abnormal, in that a tumor-like body occupied their site, or a decided excavation. In either case the meatus might be invisible or conspicuously gapping. When tumor-like, the color varied from a reddish opacity to a glistening white; the latter being caused by the electric light transillumination of very edematous tissue. Perhaps in the mouth of a bulging ureter we might see a brownish body, which could be recognized at once as one pole of a calculus. When lesser grades of protrusion occurred, with more or less marginal inflammation of the meatus, we might picture the cause as some antecedent infection of the kidney. If at some part of the inflammatory zone an ulcer existed, we were prone to believe the infection to be tuberculous. This belief was confirmed if there was marked retraction, and an irregular ulcer near where the ureteral mouth should be seen; such an ulcer had some surrounding hyperemia, and a base so uneven as to make it difficult to know which of its various recesses would give a lead for the catheter to enter the ureter. When undulating mounds of opaque reddish mucosa covered the trigonum, and obliterated all traces of the ureteric papilla, and every trace of meatus was lost, we might infer that the ureters had been discharging from faulty kidneys. When translucent ovoid bodies beset the mucosa about the bladder meatus, or that of the ureter, extravesical neoplasm was suggested. When the ureter mouths were atypical in location or number, we might infer congenital abnormality higher up. The most

important of these conditions were the tuberculous ulcer and the imbedded calculus. Diagnosis of affections of the upper urinary tract would be nothing like so complete without the use of the short flexible catheter, lying a couple of inches within each ureter. We could thus obtain the individual renal products for microscopical, chemical, and cultural examination, and perhaps supplement the test by the long ureter catheter for determination of any anatomical abnormalities of the ureter and renal pelvis. To Brenner was due the credit for first adapting the cystoscope to effect ureter catheterization. He spoke of the advantages of the bilateral cystoscope for making synchronous collections of the urines feasible. He said that it was just as necessary to know the competency of a remaining kidney as to know the full pathological condition of the one to be removed. As a means of diagnosis, the ureter catheter was valuable, (1) by reason of what came through it, (2) by reason of its contemporaneous service as a sound, (3) by its use as an *x*-ray landmark, with which to compare other questionable *x*-ray shadows, or questionable and palpable tumors. Of all bilateral catheterization tests, those which demonstrated a unilateral tuberculosis were probably a class more gratifying than any, on account of the early diagnosis, and the practical results attending nephrectomy. Among the least satisfactory catheterizations were those of renal hematuria; although the doubtful source of bleeding was determined in all, the etiological factor in more than 50 per cent. was not made out. Dr. Brown then cited a number of cases in which the use of these agents had led to a proper diagnosis.

Dr. L. Bolton Bangs said that a more careful and definite diagnosis prior to operation should be made. When palpation, combined with objective and subjective symptoms, failed to give a preliminary definite diagnosis, then an exploratory incision must be resorted to. In operating upon one kidney, he said it was very important to note whether or not a second kidney was present. In the hands of the most careful men during earlier days, and before the introduction of the more precise means of diagnosis, one kidney had been operated upon, and, at autopsy, it was learned that the patient had had but the one kidney.

Dr. B. Farquhar Curtis said that often these complicated methods of diagnosis failed. His personal experience was limited to the Kelly method of catheterization. He urged the necessity of simplifying the methods or increasing the skill of the expert, so that patients would not suffer so much in the manipulation. The laboratory findings often did not answer questions; at times the tubercle bacilli could not be found in the urine, and yet there would be present a tuberculous kidney; sometimes the urine was decomposed or filled with pus and other deposits which would obscure the microscopical examination. It must be acknowledged that simple and ordinary clinical symptoms were often misleading; often pain existed without apparent cause, and in some of these cases the kidney had been opened under the supposition that a calculus existed which caused the pain, and yet the patient had been relieved, although no cause for the pain could be found, the result justifying the operation.

Dr. Eugene Fuller said that a short time ago the diminution in the amount of urea excreted or the finding of casts was a sufficient indication to prevent one from operating upon the lower urinary tract. Now when urgent symptoms were present he did not think it necessary to postpone operation simply because urea was diminished or casts and albumin were present. In cases of obstruction, even though patients had been suffering from uremic attacks, one had better operate at once than to wait for the kidney to be further damaged; it was wonderful in how many cases the kidney lesion would repair itself when the obstruction was relieved. In ureteral catheterization he said the passing of the cystoscope through the urethra was the painful part of the procedure. It was wonderful the amount of tolerance the ureter had and how little reaction followed catheterization of it.

Dr. John F. Erdmann said he would limit himself to the consideration of intercurrent or concurrent diseases, and presented four specimens of stones with photographs of one. Three of these had been removed by operation, the fourth was passed voluntarily. The large stone gave symptoms that were supposed to result from intestinal obstruction, in fact, presenting all the symptoms which accompanied such a condition. In taking a careful history, evidences of having passed a calculus and purulent urine for some time before were obtained. A specimen passed that day contained considerable pus, sediment, and also one calculous body. The tumor on palpation appeared to be retroperitoneal, fluctuating in its main portion, and boggy in its lower. A diagnosis of perinephritic abscess was made, an immense quantity of urine and pus was liberated as soon as the fat capsule of the kidney was entered, and perforation of the pelvis of the kidney was observed, through which pus and urine were escaping. Six days later it was necessary to remove the kidney, when twenty small calculi were found in it. Three or four months later the same symptoms recurred, and the *x*-ray showed a very large calculus; nephrotomy was done through the pelvis of the kidney, and the large stone which presented was removed. The second case gave all the symptoms of appendicitis which had existed for a number of years, with the history of an attack early in life. An exploratory operation on the appendix was advised, as well as upon the ureter. A badly diseased and adherent appendix was found, and a large number of adhesions were removed from the cecum, but nothing was found in the ureter. At the end of three or four months pain occurred at McBurney's point, which was so severe as to require the use of chloroform. Free blood was found in the urine. An *x*-ray picture showed evidences of stone in the pelvis of the kidney. A nephrotomy was done, and the stone was removed. The third patient was a medical student, who passed a stone voluntarily; there was no question regarding the diagnosis. But he also had digestive disturbances, and, within a short time after passing the stone, was seized with an attack of gangrenous perforating appendicitis, for which he was operated upon, with recovery. The fourth specimen was removed from a man who gave sharp evidences of both appendicitis and kidney stone; there was no question regarding the diagnosis. The appendix was found to be adherent and involved; it was removed. The ureter was explored, and a stone was found located one and a half inches from the bladder entrance. All these patients had marked digestive disturbances; two had pronounced hematuria and one had pyuria.

Dr. Francis C. Wood believed in the slight value of the total leucocyte count in many cases of severe sepsis, and in the great value of the relative count of the different forms of leucocytes. The determination of the presence or absence of an iodophilic reaction in the leucocytes was also of great importance in a decision as regarded operative procedures. He had observed a number of cases in St. Luke's Hospital that showed that even if the total leucocyte counts were low, when the polynuclear leucocytes were relatively numerous, and an iodophilic reaction was present, pus had invariably been found on operation. He was not inclined to take a very favorable view of cryoscopy. If one relied upon the brilliant results of Kümmell, the diagnosis of renal insufficiency would appear to be a simple matter, and the determination of the possibility of an operation equally easy from the freezing point of blood. In such work the general look of the patient, the findings on physical examination, and the skill of the surgeon were most important points.

Dr. Sondern said that Koranyi and his followers believed that when the freezing point was low, it did not mean that operation should not be performed, but that no renal parenchyma, however diseased, should be removed. Probably, in cases of this kind, operation should consist in incision and drainage, but not removal of renal parenchyma.

Dr. George Gregory Cole said that out of 179 cases examined by him during the past eighteen months, only

three occurred in which he could not make either a positive or negative diagnosis, or in which the diagnosis had been incorrect.

Dr. F. Tilden Brown said that there was but little reason to doubt that these calculi which became lodged in the ureter for some time could be dislodged if the catheter could be passed in and irrigations practised. His scheme would be to have ureteral catheters of increasing sizes; if the stone became lodged well down in the ureter, laminaria tents could be introduced to dilate this portion of the canal so that the stone could escape. Any treatment that could be substituted for the extensive operations now employed for ureteral calculi would be of great value.

Election of Officers.—*President,* Dr. Charles Loomis Dana; *Vice-President,* Dr. T. Mitchell Prudden; *Trustee,* Dr. Abraham Jacobi; *Treasurer to Board of Trustees,* Dr. Reginald H. Sayre; *Committee on Admissions,* Dr. William C. Lusk; *Committee on Library,* Dr. L. Emmett Holt; *Delegates to the State Medical Society,* Drs. David Bovaird, Jr., James Ewing, Charles L. Gibson, Homer Gibney, and Edward L. Keyes, Jr.

NEW YORK STATE MEDICAL ASSOCIATION.

New York County.

Stated Meeting, December 19, 1904.

The President, Dr. Francis J. Quinlan, in the Chair.

A Memorial to Dr. William R. Pryor.—Dr. C. J. MacGuire paid a high tribute to the personal character of the late Dr. William R. Pryor, and his tireless and original work in the field of gynecology. Among those engaged in that field he occupied a place in the front rank, and probably did more than any other man in this country to exploit and make popular the vaginal method of pelvic operations.

The Treatment of Leukemia and Pseudoleukemia by the X-Rays, with Illustrative Cases.—Dr. Arthur Holding read a paper on this subject. He stated that a search of the literature showed that twenty-five cases of splenomyelogenous leukemia treated by the *x*-rays had been reported. Of these, eight patients were symptomatically cured, fifteen were improved, and two were unimproved or dead. Of eight patients with lymphatic leukemia treated by the *x*-rays that had been reported, none was cured; three were improved, and five were unimproved or dead. Of twenty-two cases of pseudoleukemia similarly treated, six patients were symptomatically cured, thirteen were improved, and three were unimproved or dead. In most of the fatal cases there was improvement in their symptoms, and some patients died of intercurrent diseases. The technique used in treating leukemia and pseudoleukemia by the *x*-rays consisted in applying the light over the spleen, the enlarged glands, the chest, knees, and elbows. The *x*-ray tube had to be sufficiently excited to give a light penetrating enough to reach the diseased organs. A low vacuum tube, expending its energy upon, but not penetrating, the skin, was to be avoided, as it was this grade of light that produced *x*-ray burns. Medication with quinine, fluorescin, and other substances, with the intent of increasing the fluorescence of the tissues, had been recommended, and might be added as an adjuvant, providing it did not interfere with more important medication. Dr. Holding then reported in detail two cases which were still under treatment: one, a case of splenomyelogenous leukemia, and the other a case of Hodgkin's disease. Both patients showed improvement under the *x*-ray treatment, relapsing when the applications were discontinued, and again improving when active treatment was resumed.

Dr. Mortimer Warren detailed the blood changes that had been observed in the two cases reported by Dr. Holding.

Dr. Edward B. Finch reported a case of Hodgkin's disease, in which remarkable improvement occurred while the patient was under the *x*-ray treatment, but in which the symptoms recurred when the treatment was discontinued. He called attention to the apparent remarkable tolerance shown by these patients to the *x*-rays, and emphasized the fact that, in order to get good results, the treatment required great persistency, and the exposures had to be long and severe.

Dr. Finley R. Cook said that while his experience with the *x*-rays in the treatment of leukemia and pseudoleukemia was limited, he had employed the method with excellent results in various forms of glandular hyperplasia. This included a case of simple goiter, and also one of exophthalmic goiter, in a middle-aged woman, in whom, after only six exposures, the enlarged thyroid totally disappeared, and there was a marked improvement in the nervous symptoms from which she had suffered. In a number of cases of hyperplasia of the spleen, mostly of malarial origin, the result of the *x*-ray treatment was highly satisfactory, and the speaker thought we would not go far astray if we submitted all cases of enlargement of the spleen or lymphatic glands to the *x*-rays, particularly when those patients had failed to respond to other forms of treatment.

Dr. Charles W. Allen said that in spite of the statements made by many to belittle the value of the *x*-rays in the treatment of certain internal disorders and diseases of the skin, he wished to add his testimony to the efficacy of this therapeutic agent in various severe and intractable conditions, such as those under discussion.

Dr. H. Grad said that while the treatment of leukemia, and allied conditions with the *x*-rays had been fairly successful, a number of failures had been recorded, and it would not do to be over-enthusiastic. In Hodgkin's disease, where we had to deal with a simple glandular hyperplasia, we could expect better results from the treatment than in true cases of leukemia, in which characteristic blood changes were present, which could scarcely be radically influenced by radiotherapy. The rays exerted a remarkable effect on tissue, but it was doubtful whether they could influence a process like that underlying leukemia.

The Abuse of Water Drinking.—Dr. Morris Manges presented this paper. He stated that the abuse of water drinking was not, as was usually supposed, an American vice, but was practised in every part of the world. It was not confined to the city, and was seen in its full glory at the various mineral springs, where the temptation to "drink all you wanted for five cents" seemed to be too great to be resisted. Water once within the body was no longer water, but had to be considered in its relations to the various salts, colloids, etc., with which it came in such intimate contact. The normal quantity of water for the healthy adult individual, exclusive of the water contained in the food, was about one and a half to two quarts per day. Of this, two-thirds appeared in the urine. Only a small portion of the water was absorbed by the stomach, the maximum quantity being 10 per cent. The other 90 per cent. passed on into the intestines. Every drop of water introduced into the system had to be excreted from it, directly or indirectly, by the heart; hence the larger the quantity of liquid introduced, the greater the amount of energy demanded of the heart for its disposal. Water drinking affected chiefly (1) metabolism, (2) the temperature, (3) the circulation, especially the heart, (4) the glandular secretions, and (5) peristalsis. The most striking abuse of water drinking was in chronic nephritis. Investigations made by von Noorden and others had shown that when the heart was no longer competent, the daily quantity of water should be restricted to one and one-quarter litres, not including the water contained in the food, which averaged from 500 to 700 c.c. In the earlier stages, also, when good compensation existed, this restriction was advisable as a prophylactic measure. Von Noorden had also observed cases of chronic parenchymatous, and even acute, nephritis, in which the restriction of water had been found useful, and Baruch had emphasized the importance of this measure in acute nephritis. In heart disease the abuse of fluids was less evident, but none the less serious in its consequences. The chronic hyperemia of the kidney, the existence of dropsy, and the hydremic plethora and anemia in advanced cardiac conditions were sufficient indications for warning patients against the use of too much

liquid. Every drop of water taken into the body meant additional work for the heart. The aim should be to regulate the blood pressure in the kidney, rather than to crowd more work upon the already struggling heart. In chronic gastric, and intestinal disorders, the significance of the abuse of water drinking could be more readily recognized. As regarded the effects of large quantities of water in metabolic disorders, the abuse of water drinking would continue until patients and their physicians worshiped at other shrines than that of uric acid. Rubner, the distinguished Berlin physiologist, had shown that copious water drinking might for a short time cause a washing out of nitrogenous products from the body, but water had no effect upon the splitting up of the albumins, and upon general metabolism. As regarded free flushing for the removal of calculi, gravel, etc., it was important first to ascertain the condition of the circulation, and to verify the fact that the increased intake of water was represented by an adequately greater amount of urine. If this failed to occur, an investigation into the cause of the failure should be made before blindly ordering more water. If the necessary rise in the renal blood pressure had not been obtained, it was much better to resort to cardiac tonics, with or without the alkaline diuretics. In acute infectious diseases, and in septic conditions, in which free diuresis meant so much in the successful outcome, it was also necessary to guard against the dangers which followed from crowding too much water at ordinary temperature into the patient's system. Those patients were already on a fluid diet, and the motor and secretory functions of the stomach were lessened as a result of the fever. Any abuse could be guarded against by carefully watching for evidences of dilatation of the stomach. The water should always be given cold, and in small quantities frequently repeated.

Dr. Simon Baruch said the greatest abuse of water drinking was the inexact manner in which this therapeutic measure was prescribed by physicians, What was true of water in its external application was tlso true of its internal effects. The effects depended upon the temperature of the water, its quantity, and the duration of the application. A fainting woman might be revived by a sprinkling of cold water, but if we immersed her in a tub of water of the same temperature for any length of time, there would probably be a collapse. It had been shown that small quantities of cold water stimulated the flow of gastric juice, while large quantities paralyzed the peristaltic action of the stomach. The physician, when he instructed his patient to drink water, should prescribe the exact quantity, and the time and temperature at which it should be taken. In certain fevers, especially when there was already a retention of water in the system, the ingestion of large quantities of fluid should be avoided, because the heart was overburdened and weakened by the toxins of the disease. In such cases. small quantities of moderately cold water, taken at regular intervals, had a diuretic action and gave much better results. This rule did not apply to conditions like cholera or hemorrhage, in which there was an actual loss of water, and where flushing was one of the best therapeutic measures.

Dr. Alfred Meyer emphasized the importance of treating the individual as well as the disease. The abuse of water drinking, to which Dr. Manges had called attention, was no greater than the abuse of egg eating among those suffering from tuberculosis, and the results of such excess often gave rise to more trouble than excessive water drinking. The speaker referred to the dangers of overindulgence in surf-bathing, of which he had frequently seen examples at the various coast resorts during the summer. Aerated waters, which were apt to cause dilatation of the stomach, should be avoided in certain cardiac conditions, especially angina pectoris.

Dr. Beverley Robinson said that in the treatment of typhoid fever and the acute exanthemata with high temperature, he still favored the use of a goodly quantity of water taken internally. Such patients usually craved water, and he saw no reason why it should not be given freely. Under such conditions he did not think it affected the heart injuriously, nor that it acted otherwise than advantageously. On the contrary, the high temperature and the toxic condition of the system were apparently favorably affected by a plentiful supply of water. In regard to dosing old nephritic or cardiac cases with large quantities of water, Dr. Robinson said he did not think such a practice was common among up-to-date physicians. Fluids in any form should be given sparingly when the system was already overloaded with water, and in the early stages of acute nephritis.

Dr. Charles C. Ransom said there was no better stimulant to metabolism in chronically diseased conditions than water, properly used. The reason he thought it was not more generally prescribed was that there was a lack of knowledge regarding its therapeutic value. In the treatment of gout he did not favor the drinking of sulphur water, or waters of that class, and he had seen better results from the external use of water than from its internal application.

Dr. Charles B. Fitzpatrick said he did not think there was much abuse of water drinking in New York City. The abuse of alcohol was more common, and this, together with the infectious diseases, was responsible for most of the diseases of the kidney. In certain types of nervous disease, Dr. Fitzpatrick said he had employed large quantities of water, with very gratifying results. The free use of water internally was also of value in certain toxic conditions. In diphtheria, for example, the cause of death was a fatal dose of the toxin, and by diluting this sufficiently with water, its lethal effects might be put off until other means could be employed to combat it.

Dr. Manges, in closing, said he thought there was no doubt that in chronic nephritis there was much abuse of water drinking. The point he wished to emphasize in his paper was that an increased intake of water should be represented by an adequately greater amount of urine. If this failed to occur, an investigation into the cause of the failure should be made.

The Influence of Sugar on Fermentations in Milk and Milk Curds.—H. L. Russell declares that it is apparent from work that he has done on both milk and curd that the nature of the fermentations normally set up in these nutritive media depends very materially upon the composition of the same. Both of them are rich in nitrogen and, therefore, exceedingly susceptible to bacterial activity. Ordinarily such media would naturally undergo putrefactive changes, but the presence of milk sugar evidently prevents these organisms from reaching their maximum development on account of the acid which is formed by the growth of the lactic bacteria. When the milk sugar is removed, the lactic bacteria are still capable of growth, but under such conditions little or no acid is formed, and, therefore, the conditions do not become so unfavorable for the growth of the nitrogen-decomposing class. The lactic bacteria, therefore, are of importance in the prevention of putrefactive changes in milk by the action which they exert on the milk sugar. These studies have an important bearing on infant feeding. If conditions arise whereby the lactic bacteria are not able to develop, if they are overpowered by the growth of other species, the character of the fermentations produced is materially different, according to the writer. The most important condition that determines the probable type of development is the presence of the sugar. This factor may enter into the distinction between cow's milk and mother's milk. The first is higher in nitrogen and lower in sugar, and hence may not be so suitable for growth of lactic species. The beneficial use of foods consisting largely of carbohydrates, in the treatment of infantile disorders, such as summer diarrheas, may be an application of this principle that the sugar exerts a protective effect on the character of the fermentations produced.—*Archives of Pediatrics.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending December 31, 1904:

	Cases.	Deaths.
Measles	126	6
Diphtheria and Croup	302	45
Scarlet Fever	206	16
Smallpox	...	....
Chickenpox	87	...
Tuberculosis	434	134
Typhoid Fever	52	7
Cerebrospinal Meningitis		18
Typhus Fever	.	..
Yellow Fever	.	.
Cholera		. ..
Totals	1 207	226

The Functions of the Tonsils.—George Bacon Wood finds that the tonsillar tissues possess distinctly two properties: They can absorb fluids and finely divided solid particles from the crypts; the other property they hold in common with all adenoid tissue, namely, the production of lymphocytes in the secondary nodes or follicles. The writer thinks that the truth of the following propositions has been practically established: The older forms of leucocytes are derived by a continuous development from the younger lymphocytes. The lymphocyte is originally derived from epithelial structures. In this connection the thymus gland plays the most important rôle. There exists strong histological evidence that lymphocytes are directly derived from the epithelium of the tonsillar crypts. From the results of these investigations, therefore, the writer believes that the tonsil is a primogenial source of leucocytes. He states that the strongest argument against the theory of leucocytic primogenesis as the function of the tonsillar structures of the throat is that the idea is too revolutionizing. The thought that the epithelial lining of he tonsillar crypts may be converted into cells that are by most pathologists supposed to be of connective-tissue origin is not one to be accepted lightly. It suggests the possibility of the interchange of cell types. Such a theory would undoubtedly readily explain many difficulties necessitated by our present methods of classification, especially in tumor types. As to the tonsils, if we accord to them the function of leucocytic primogenesis, their presence in the human economy is beautifully explained. The leucocytes are closely connected with various tissue changes, and the tonsils are the largest and best developed when tissue change is most active, that is, in childhood. The thymus gland develops in early embryonic life and gives rise to the first leucocytes. When it atrophies, the tonsillar tissues develop, carrying on the same function. Finally, the writer suggests that all adenoid tissue which has developed in intimate relation with the epithelium, is playing a rôle similar to this of the tonsils; that is, that the gastrointestinal follicles, the adenoid tissue of the appendix, and the like may do the work in the adult which the tonsils of childhood had usurped from the embryonic thymus. The writer states that what he has written stands simply as a suggestion concerning the function of the tonsils.—*University of Pennsylvania Medical Bulletin.*

Practical Points in Abdominal Surgery—Peritonitis.—Bayard Holmes states that excluding the rare possibilities of a chemical or a mechanical peritonitis, this disease is always due, in the clinical sense at least, to some form of infection. This disease is interesting to the physician and surgeon only so far as its prevention is possible or its course is limitable. The most common source of peritonitis, especially in the male and in children, is the vermiform appendix. The second most common source of peritoniti[s] confined entirely to adult females, and is limited to the uterus and fallopian tubes. Probably the third site of a beginning peritonitis is the region of the gall-bladder and common duct. All operators agree that there is no expectant treatment of peritonitis; that the prime imperative duty of the attendant is to remove or obliterate the source of peritoneal infection at the earliest possible moment, remove the disseminated infection as completely as possible, and place the peritoneum and the patient in the best possible condition for recovery. There is practical unanimity in the immediate removal of the source of infection. In regard to the removal of the escaped infection, two methods are offered: the dry method and the method of irrigation. The latter has always been considered a dangerous procedure by the writer. In regard to placing the peritoneum in the best condition for recovery, there are two methods: drainage, and complete closure without drainage. Notwithstanding all of the arguments in favor of closure, the writer still follows the other method. One of the most threatening symptoms of peritonitis is intestinal obstruction. When drainage will not overcome this condition, an artificial anus must be made. As a rule, it closes in the course of a few weeks, or it remains and must be treated surgically.—*Illinois Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended December 31, 1904:

THE DISEASES OF THE ISTHMIAN CANAL ZONE.*

BY RICHARD LIGHTBURN SUTTON, M.D.,
ASSISTANT SURGEON, UNITED STATES NAVY.

A MOST excellent opportunity for the clinical study of tropical diseases is presented to a large number of young American physicians with the commencement of work on the new interoceanic waterway. Information concerning the diseases to be encountered, and the conditions that must be met will undoubtedly be acceptable to many.

Any preconceived ideas which the newcomer may have formed regarding either the people or their ailments are very liable to undergo a considerable metamorphosis within a few weeks after his arrival on the Isthmus. The practitioner who expects to find a case of "yellow jack" or blackwater fever in every native clinic he conducts will be greatly, if agreeably, disappointed. These diseases are undoubtedly present at times, but one encounters them much more seldom than the average reader would be led to imagine.

Taking everything into consideration, malaria is probably more frequently seen than any other affection. This does not hold true with regard to foreigners who have but recently arrived, but as they are greatly in the minority at present, we will discuss the various types of paludism first. Long continued residence and many attacks of malaria have combined to render the older inhabitants partly or wholly immune to the infection. The disease is encountered very frequently, however, among the children, from earliest infancy to adolescence, and foreigners almost invariably suffer from repeated attacks.

The adult natives, while free from any outward manifestation of the affection, practically serve as walking laboratories for the propagation of the plasmodia, thus affording the industrious and ever ready mosquito an opportunity to transfer the parasites to a more fertile soil.

If possible, the microscope as an aid in the diagnosis of this and other affections should always be used. It may not prove amiss to describe briefly the technique of blood examination which we have employed with the greatest degree of satisfaction.

The lobe of the ear, from which practically all of our specimens were obtained, is first cleansed with a moist piece of soft gauze. No antiseptic is needed. A quick jab is given with a Hagedorn needle, the first drop of blood is carefully wiped away, the second is caught on the margin of a smooth square of cigarette paper, and slowly drawn across the surface of a clean slide, giving a moderately thin, even smear. A needle or the edge of a cover slip may be used for spreading, the drop of blood being first collected near the end of the slide, but the above procedure has given us the best results. There is no comparison between the advantages gained by using the large slides, and the results obtained when only small cover slip preparations are employed. One can obtain better and more evenly smeared spreads on the larger surfaces, the slides never break in cleaning, and can be used repeatedly, the larger area of the field permits an accurate differential white count to be made from the same specimen, and, in addition, the great number of red corpuscles which may be examined in the single preparation render a search for malarial organisms, especially if the parasites are extremely few in number, much more rapid and certain. The examination is made with the intervention of nothing whatever, except the immersion oil, between the 1-12 objective and the stained corpuscles. Both the Abbé condenser and mechanical stage should be used.

Fresh blood specimens are extremely unsatisfactory, and are not to be relied upon. Such examinations are, of course, better than none at all, but the findings, unless the observer be a professional microscopist, are disappointing in many instances when a well stained mount would quickly furnish the desired information. The Wright stain, now so popular in the United States, gives entire satisfaction. Care must be taken, however, to keep the bottle tightly stoppered when not in use, and, even with this precaution, more methyl alcohol must be added at frequent intervals to take the place of that lost by evaporation, thus preventing too great concentration of the stain.

With regard to the types of malaria represented, the estivoautumnal is the one by far most frequently seen. A large percentage of these cases, fully three-fifths, show hyaline rings. Contrary to the experience of some observers, one generally has very little difficulty in picking up these forms in well stained specimens. Quite a large number of the estivoautumnal parasites containing pigment are found, but hyaline ring forms combined with crescents, or the latter alone, are rather rare. The close relationship between estivoautumnal infections and fevers of a pernicious character should always be kept in mind.

In several instances which have come under my observation the symptoms were not directly indicative of malaria at all. The temperature was but slightly elevated, normal or even subnormal, while neuralgias, headaches, and rheumatic manifestations were present. In one case, which occurred last June, the symptoms were those of algid malaria. The onset was marked by a convulsion, the occurrence of explosive vomiting, feebleness, prostration, the passage of highly colored urine (only a trace of albumin, however), and the skin was covered with cold perspiration. The temperature was slightly subnormal (97.6° F.), pulse 110 and feeble. The presence of the parasite (extremely small, delicate, and non-motile, lying in somewhat shrunken red cells), was demonstrated, and fairly rapid recovery followed the hypodermic use of rather heroic doses of quinine bisulphate.

The tertian type of the infection occurs next in

*The writer is indebted to his former senior medical officer, Surgeon Dudley Newcomb Carpenter, U. S. Navy, for much information and advice concerning data and case papers.

frequency. Full grown segmenting forms are often encountered, and some beautiful specimens may be obtained. In native children this type seems to be the predominating one, a half dozen adult parasites oftentimes being found in one field. The tertian rosettes are large, clear cut, and usually contain from fourteen to thirty spores. All found thus far have been intracellular, although their appearance in fresh specimens gives one the impression, at times, that they are lying outside the cell wall. None of them contains so large a number of spores (forty or fifty) as the rosettes described by Marchiafava and Bignami.* The tertian hyaline forms appear to be rather infrequent.

Mixed tertian and estivoautumnal fever is rarely seen, and no case of quartan infection has been discovered.

Patients suffering from advanced degrees of malarial cachexia are often met with, especially in the large native clinics, where representatives from the more remote districts apply for treatment. The hæmoglobin percentage in these instances is very low, from 30 to 70 per cent. (Talqvist), while the red cells are over 4,000,000. There is but slight, if any, leucocytosis, and the differential count shows a decided increase of the large mononuclears and transitionals. The most prominent symptom is the enormous splenic enlargement. I have never had the opportunity to do an autopsy on one of these cases, but the physical signs show the spleen extending well down into the left inferior abdominal quadrant, and forward almost to the median line. The organ is extremely solid, with smooth, rounded margins. Owing to mechanical interference by pressure, as well as the impoverished condition of the blood, there is considerable cardiac and respiratory disturbance, and it is usually for the relief of one of these conditions that the physician is consulted. The temperature is seldom over 100° F., and a history of recent typical malarial manifestations is often indistinct or absent. The tendency to excessive hemorrhage from even slight wounds is noticed in these cases, but the predisposition is no greater than it would be in temperate climates.

Arsenic, with or without iron, is of more benefit than quinine, but the anæmia and splenic enlargement do not respond well to any treatment. If it were possible to keep the patient continually under observation so one could see that the medicinal, dietetic, and hygienic measures ordered were enforced, the results would be more satisfactory.

The use of quinine as a prophylactic in all varieties of malaria is undoubtedly of great value. From two to five grains should be administered three times daily. Protection from mosquitos by means of fine mesh netting, and the burning of pyrethrum powder should also be insisted upon, and the usual modern methods to prevent the breeding and multiplication of these dangerous little pests should be employed.

Dengue is the disease which most frequently attacks the new arrival in this country, and even the more thoroughly acclimated natives do not wholly escape it. The initial symptoms vary, but, in the order of their value, they may be given as follows: (1) Sudden onset; (2) Severe and continuous supraorbital headache; (3) Deep congestion of face and neck; (4) Backache, together with severe pain in the region of the loins. Chilly sensations, seldom a distinct chill, may precede the first rise of temperature. The primary and terminal eruptions, upon the diagnostic value of which so much stress is usually placed, are absolutely unreliable here, being absent, especially the secondary one, in the majority of instances. The disease is extremely contagious,

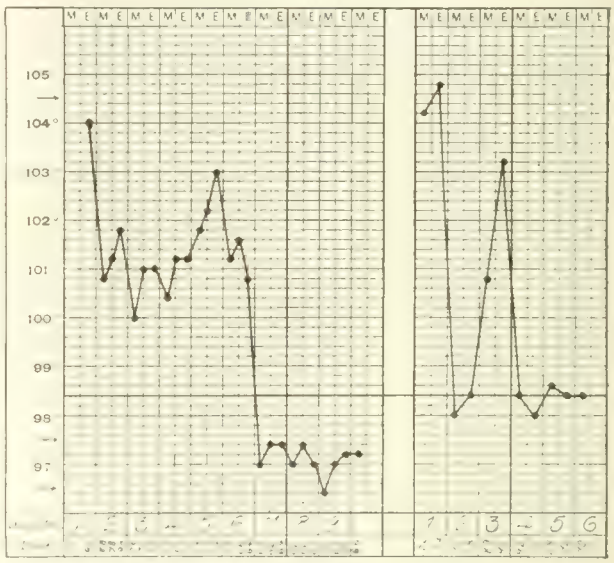
*Ueber die Varietäten der Malariaparasiten, *Deutsche medizinische Wochenschrift*, 1892.

and many persons in the same place are usually attacked at the same time.

If a microscope is available, total and differential counts should be made. There is a leucopenia from the first, the whites sometimes being less than 2,500, there is little or no destruction of the red cells (4,200,000 to 5,500,000), and the hæmoglobin index is usually 1 or 1.+. The differential white count will show the proportion to be about normal on admission, later, and especially by the beginning of convalescence, a marked small mononuclear lymphocytosis will be noted, which persists for several days.

Stage of Disease.	Polymorphonuclears	Large Mononuclears	Transitionals	Small Mononuclears	Eosinophiles	Mast Cells
On admission...	32.2	7.9	36.6	23	0	0.3
First drop.....	41	5.4	6.7	46.8	0	0
Second rise.....	50.8	7.0	5.2	33.0	4	0
Second drop....	52.5	5.9	5.4	25.1	11	0
Convalescence ..	50	5.3	4.2	30.3	9.7	0

An eosinophilia, sometimes reaching as high as 12 per cent., sets in just after the second rise. The table shows the changes in the differential leucocyte count at various stages of the disease. There is sel-



THE FEVER CURVE IN DENGUE.

A, an [illegible] chart [illegible]; B, the temperature and pulse in a typical case of dengue.

dom any splenic enlargement; in over two hundred cases we have found the organ palpable only three times. Occasionally, in atypical dengue, it is extremely difficult to make a positive diagnosis. If albumin (which is of infrequent occurrence) is present in the urine, or the gums be spongy and tender, or there is a discrepancy between the temperature and pulse curves, such as was found in one patient who came under observation, the condition may be strongly suggestive of yellow fever. If the clinical resemblance is sufficient to justify even a doubtful diagnosis of the latter, precautions should at once be taken with regard to double screening, and isolation from mosquitos. While the symptoms given are present in the majority of instances, there may be marked variations from the typical picture at times. The onset is occasionally insidious, with catarrhal symptoms predominating. The patient will apply for treatment because of a bronchitis, or a rather persistent diarrhœa may be the cause of complaint. The disease is a self-limited one, and treatment, except to lessen the discomfort, is of no avail. A brisk cathartic, with phenacetin or acetanilid, and an ice-bag to the head are the most efficient remedial agents we have found. One attack only partially immunizes.

The sequelæ are frequent, stubborn, and often severe. The fever may be followed by sciatica, in which case the removal of the sufferer to a cool climate has given the best results, or a tropical bubo may appear within a few days following the return of the temperature to normal. Facial neuralgia, herpes, myalgia, bronchitis, corneal ulceration, or symptoms of mental disturbance often follow in the wake of a severe onslaught. As in the influenza of our temperate climates the toxin seems to have a special affinity for the nervous centers.

Beriberi, a multiple neuritis, seen most frequently in the wet lowlands and marshy districts, thrives in this part of the tropical world, especially affecting the Chinese contingent. More cases are to be found among this one race than all of the others put together, although the native Panamanians do not entirely escape. Both the dropsical and paraplegic forms are seen, often the two associated. No instance of the malignant type has come under my observation. In the earlier stages one finds the exaggerated knee jerk soon followed by complete loss of the patellar reflex, the paraesthetic areas over various parts of the body, and the signs of beginning muscular incoordination indicative of the involvement of peripheral nerve trunks. Later, cardiac dilatation and irritability, with œdema of the extremities, and an ataxic gait are added to the above, making a diagnosis easy. Unfortunately the disease must be recognized early if much benefit is to be derived from treatment. Removal to the more sanitary locations afforded by the tops of the surrounding hills, a nutritious diet of nitrogenous matter, fats, and sugars, with strychnine and other tonics, probably comprise the best and most available measures under the circumstances.

Infection with intestinal parasites is the rule, not the exception. One is able to find the eggs of a half dozen different varieties in nearly every fecal specimen examined. The almost universal presence of these protozoa in the intestinal tract is due to the lack of personal cleanliness among the majority of the inhabitants, and also to the character and methods of preparation of their food. The use of impure drinking water also gives rise to the trouble in many instances. The well water at Emperador was highly prized for its flavor (it was drained from the surrounding square of houses and stables), and when tested for nitrates gave a deep ruby red color. The eggs of the entozoa found are those of *Oxyuris vermicularis, Tricocephalus trichiurus, Ascaris canis,* and *A. lumbricoides, Strongyloides intestinalis,* and *Uncinaria duodenalis.*

The last named, identical with *Sclerostoma duodenale* of Cobbold, is by far the most important and dangerous of all. Especially is this true if early treatment is not instituted. The recognition of an infected case is easy, in fact, one can almost make a diagnosis at a glance. The patient is emaciated and cadaveric, lacking in strength and vitality. The skin is lemon tinted, the visible mucous membranes are pallid, the hair is dry and brittle, and, oftentimes, the eyes are as prominent as in a case of exophthalmic goiter. Cervical pulsation is noticed in the majority of instances. There is often œdema of the extremities, cardiac palpitation and epigastric pain are frequent, and there is usually a history of blood-streaked stools, with the passage of much undigested food material in the fæces. A loopful of the latter, thinly spread on a slide and examined with a low power, will exhibit myriads of eggs. The blood in these cases shows an extreme grade of anæmia (hæmoglobin from 20 to 60 per cent.), and the exuding drop is very tenacious and almost white in color. The eosinophilia is the highest that has ever come under my observation, seldom being under 20 per cent., and, in one instance, it was slightly over 65 per cent. Poikilocytosis is common, megalocytes and microcytes are often seen, and twice, in advanced cases, there was leucopenia (1,900 and 2,050). These cases respond well to treatment. A large dose of castor oil is given, and, after it has acted thoroughly, three twenty-grain doses of thymol are administered at two-hour intervals. No solid food is to be taken during this time, and especial stress must be placed upon total abstinence from alcoholics. Following the last dose of thymol a brisk purge is ordered. This course should be repeated in three weeks, if necessary. The after treatment consists in the use of Blaud's pills, arsenic, and a full, nutritious diet. Personal cleanliness should be enforced when possible.

One of the most troublesome insects on the Isthmus is the "jigger" (*Pulex penetrans*, Linn., *Rhynchoprion penetrans*, Oken). The favorite point of attack is one of the interphalangeal folds of the toe, and the resulting inflammation and pustular swelling give rise to great pain and exquisite tenderness. The lesions, even after the insect is carefully extracted by means of a fine needle, heal slowly. Local applications of turpentine to kill the parasite, followed by the use of mild antiseptics, or zinc oxide ointment, have been fairly satisfactory. As a prophylactic measure, the feet and legs should be protected by boots or well fitting leggings. The local use of some one of the essential oils will also be of benefit.

Snakes, centipedes, and spiders are numerous, but the danger from them is not great. The two last named seldom molest any one, and, if they do, the result has proven to be no worse than the sting of a hornet. Formalin, locally, will have both an analgesic and an antiseptic effect.

Heat exhaustion and sunstroke occur more often among the Americans than any other class. The former, with its resulting symptoms of subnormal temperature, weak, thready pulse, and severe cramps in the limbs and abdomen, is best treated by hastily covering the patient with warm blankets, administering whiskey, nitroglycerin or strychnine hypodermically, and briskly rubbing the abdomen and extremities with some stimulating lotion. The last mentioned procedure is of great value in relieving the pain.

Thermic fever is a more serious condition. The symptoms are identical with those in the cases of sunstroke in our eastern cities, and the same methods of treatment are to be employed. The rectal temperature ought always to be taken. It is far safer, and much more reliable.

Dysentery, one of the scourges of the old French canal company, is still much in evidence, especially among the natives. During the past year very few of our troops have suffered from it, principally because of the rigidly enforced rules regarding the use of only such water as has been passed through the Forbes-Waterhouse sterilizer. Every man who goes out of camp must carry a freshly filled canteen with him, and the danger of drinking from wells and fountains has been so frequently pointed out that the marines may be safely trusted to leave suspicious water alone. The disease is of both types, the acute specific, due to Shiga's bacilus, and the amœbic, with the former predominating. In only a few instances did an examination of the fecal matter show the presence of Lambl's organism. The chronic form of amœbic infection, in which the symptoms of constipation alternate with a slightly purulent, or blood-specked diarrhœa, usually gives rise to emaciation, but it is not so extreme as in the acute

amœbic variety. In the acute stage the internal administration of sodium sulphate in cinnamon water, with turpentine stupes locally, and enemata of starch water and laudanum, followed by warm decinormal salt solution constitute the best treatment. Later, copious rectal injections of quinine bisulphate (2 to 4 per cent.—weaker solutions do but little good), are indicated. In the old chronic cases the quinine is also beneficial, but solutions of silver nitrate give better results. The question of food is an important one, a single dietetic indiscretion may undo the good brought about by weeks of careful medication. Contrary to our expectations, hepatic abscess, which is so often a sequel to these infections in the far East, is seldom encountered here.

Panama is one of the few southern countries in which acute and chronic articular rheumatism occur. These joint affections are of practically the same character as those encountered in the temperate climates, and the response to the salicylates is fairly good. Myalgia, especially of the lumbar muscles, is frequently encountered, malarial infection probably being the causative agent in many cases, and dengue in others. The treatment is unsatisfactory. Quinine, until the physiological effect is produced, should be given—alone or combined with antirheumatics.

Now that the zone is under American rule, the wandering cases of leprosy, which were formerly quite frequent, will seldom be seen. Their movements will probably be restricted to a small area of territory set aside for their use. Several unfortunates, principally Chinamen, applied for treatment at Emperador. In one case large numbers of the bacilli were found in the nasal discharge. Both the nodular and anæsthetic varieties are seen, and some of the patients are extremely pitiable. Considerable improvement appeared to result from the administration of mercury in one instance, but we were unable to continue the treatment for a sufficient length of time to notice much change.

Smallpox makes occasional inroads, the crowded and unhygienic condition of many of the villages furnishing an ideal opportunity for an outbreak of such a disease.

Yellow fever, as may be seen from the health reports of Colon and Panama, is not at present epidemic in this region, and sporadic cases are seldom seen. Stegomyia mosquitos are to be found in enormous numbers.

Owing to the splendid results following the efforts of the chief sanitary officer and his corps of assistants, the Isthmus is now in a better condition, from a hygienic standpoint, than it has ever been, and, taking even the peculiar character of the climate into consideration, the health of the inhabitants will soon compare favorably with that of the residents of any extreme southern country.

Women Doctors in Russia.—New statutes which have just been issued in Russia place women doctors on practically the same footing with regard both to education and to practice as their male rivals. Women may now obtain diplomas, pursuing their studies for medical degrees in the universities of the country, and in the Military Medical Academy. A characteristic point in the new law is that it limits the number of women medical students of the Hebrew faith to three per cent.—*Australasian Medical Gazette.*

THE VALUE OF PUBLICITY REGARDING TUBERCULOSIS.*

By DENSLOW LEWIS, M.D.,

CHICAGO, ILL.

PRESIDENT OF THE AMERICAN ASSOCIATION OF LIFE INSURANCE EXAMINING SURGEONS; VICE-PRESIDENT FOR ILLINOIS OF THE INTERNATIONAL AMERICAN CONGRESS ON TUBERCULOSIS.

It is impossible to guard against an unknown peril or withstand the onset of a hidden foe. Our first duty in the case of tuberculosis, as in the case of all other conditions that militate against the health and happiness of humanity is to give notice of the existence of danger, to exploit the details of a possible attack, to discover and make manifest the methods of invasion, to arm the citadel against assault, and finally to make known that method of warfare, once the conflict has begun, which experience has shown to be the most efficient in overcoming the forces of the enemy. Our first duty is to tell the truth.

It was my privilege to be present at the initial meeting of the Chicago Society for the Prevention of Consumption, presided over by Mayor Harrison. I protested against the name. My friend, Dr. John A. Robison, told a story. He said a man went into a store to buy a pair of shoes. The storekeeper asked: "What is all this talk about tuberculosis?" The man replied, "They mean consumption." "Well," said the shoemaker, "why don't they say so?" This story convinced the majority of the members present. They voted to use the word consumption instead of tuberculosis. And so to-day our society tells only a portion of the truth. In my judgment, the shoemaker in the story went decidedly beyond his last, and by the very name our society adopted we cripple our usefulness by recognizing only one localization of tuberculous infection.

What is the truth regarding tuberculosis? We do not know it all as yet, but some things we do know. Enough is known to enable us to advise prophylactic measures which a sufficient experience has demonstrated to be of value, and a method of treatment which has proved successful enough to warrant its continuance. Furthermore, as we approach the borderland of actual knowledge, we recognize that scientific deduction permits various recommendations which, from our knowledge of infection in general, and our recognition of the results of clinical experience, must also be of value and importance in reference to tuberculosis.

What of the facts? More deaths occur from tuberculosis than from typhoid fever, diphtheria, whooping-cough, measles, scarlet fever, and smallpox combined. Most of the deaths occur between the ages of 18 and 40 years, in the active working age, during the period of greatest usefulness. Fully one-tenth of all mankind die of tuberculosis, the estimated mortality for the United States being 200,000 per annum.[1] In Illinois alone it has been estimated that the loss of money invested in children who die of tuberculosis under the age of twenty years is $1,187,800; the loss to the State from the inability of the tuberculous to perform labor amounts to $30,000,000; the loss of savings of those who die before the end of the producing age, $5,129,000, and the cost of the care of those sick and comparatively helpless, $225,000, making an annual economic loss to the State of $36,551,000 each year.[2] Nor is this all, for in cases that recover there may be serious and often protracted morbidity, and in the fatal cases there is, on our part, the distress of body and anguish of mind which cannot be estimated, as our

* Presented to the American Congress on Tuberculosis at its meeting in St. Louis, October 3 to 6, 1904.

loved ones, perhaps after years of suffering, go down to death.

The cause of tuberculosis is the tubercle bacillus. This germ may gain entrance into the body through the lungs, the alimentary canal, or the skin. It exerts its well-known deleterious effect if there is found a soil suitable for its development and environments favorable for its growth. Such conditions exist when there is debility from any cause, or when unhygienic surroundings are present. This relationship should be well understood by everybody. The tubercle bacillus thrives with difficulty or not at all in healthy individuals under hygienic conditions. It finds an admirable culture medium in individuals whose vitality is lowered from any cause, or whose mode of life or environment is unsanitary.

Tuberculosis is communicable by dissemination of the bacillus. It is not infectious to the same extent as smallpox, measles, and some other diseases, nor is it dangerous to mankind unless there is prolonged exposure under conditions favorable to the propagation and development of the germ. The panic that has occurred in certain health resorts frequented by tubercular patients is as absurd as it is unwarranted, and the restrictive measures that have been proposed in several localities are unjust and unnecessary.[3]

The recital of these elementary facts regarding tuberculosis is not intended for the edification of this distinguished and learned assembly, nor for the enlightenment of the profession. I venture, in mentioning in this connection what may be called the essentials of our knowledge regarding tuberculosis, to direct attention to the simplicity with which may be promulgated important facts concerning etiology, life history, and mortality as well as suggestions relative to prophylaxis and treatment. These essentials should be known by everybody. In the public school, in the family, in the secular, religious, and professional press, in season and out of season these truths should be enunciated until the whole world realizes the danger that is imminent and seeks safety in increase of knowledge regarding the peril that is ever present.

The matter of first importance is to help the people to help themselves. First of all, let them know the truth. Let them realize the nature of this dread disease, its mode of onset, its course, its dangers to the individual infected and to others who come in contact with him, and above all else let there be a thorough understanding of the conditions that favor the development and spread of the bacillus which is its exciting cause. In the dissemination of the truth regarding tuberculosis the value of publicity is incalculable. Our fear of this devastating plague is allayed because its nature is understood. Its advent is anticipated, for the danger signals are seen in time. The predisposing causes are appreciated; the premonitory symptoms are recognized; prophylaxis is encouraged, and rational treatment is instituted without delay. In addition, the patient with tuberculosis is taught to defend himself against his disease, and is brought early under conditions which make possible his recovery. These results are attained by a consistent and well-advised publicity. In the promotion of judicious knowledge regarding this subject, which affects the well-being of all mankind, I offer respectfully certain considerations, which are the outcome of my experience and observation in different countries of the civilized world. I advocate publicity regarding tuberculosis, but I also beg leave to insist on the promulgation of knowledge relative to life itself, and, as a protective measure to all, I venture the assertion that the State must eliminate, as far and as rapidly as is practicable, those conditions which modern science has demonstrated to be inimical to the welfare of its citizens. The constitutional guarantees which refer to life, liberty, and the pursuit of happiness, must not be invoked to interfere with the plain duty of the State in enforcing salutary measures which tend to ameliorate the condition of humanity.

Health is of supreme importance. The best heritage a child can receive is a sound constitution, and the best education that can be given is the systematic development of bodily functions, and their consistent correlation.[4] Disastrous in the extreme are the consequences of any deviation from the strictest concern for this most important matter in the child's development. Education, as the term is generally understood, is a failure and a farce if due regard is not had for the child's well-being. All that may be learned is the veriest folly if health is lost in the learning. All the accomplishments of the world are valueless if, in their acquirement, the constitution is undermined.

It is no longer believed that tuberculosis is hereditary, except in very rare instances, when the bacilli gain access to the body before birth—the so-called cases of congenital tuberculosis, nine or ten instances of which, according to Osler, have been described in man. The infant, however, is capable of being infected from the first moment of its birth, and it is found, both with infants and with calves, that if they are removed at once from tuberculous mothers, they remain free from tuberculosis.[5]

The infant of a tuberculous mother must be provided with a healthy wet-nurse or fed on modified milk. Without here theorizing in regard to the relationship of bovine to human tuberculosis, it is proper to say that it is the part of wisdom to pasteurize all cow's milk supplied to infants. Knowing the high mortality of all infantile life, and realizing that the infant of a tuberculous mother, even if free from tuberculosis, is likely to be debilitated, or at least relatively deficient in vitality, it is imperative that such an infant shall receive special care, and be placed early under the best hygienic conditions. In several large cities provision is made for a free distribution of pure milk, and everywhere a sterilizer should and can be made available even to the poorest citizen. All municipalities can prohibit the sale of impure or adulterated milk, not alone because of the possible presence of the tubercle bacillus, but chiefly because of the importance of supplying a nutritious food upon which the infant may thrive. All infants are potential citizens of the State, and have the right to live. If the home is unsanitary, if the infant for any reason cannot there receive the special care that its welfare demands, a temporary home should be provided, very much on the plan that has been adopted in the case of the illegitimate,[6] so that this inherent right of the infant shall not be abrogated. Such a provision, moreover, enables the State to fulfil its manifest duty to act, when necessary, *in loco parentis*, in the case of all dependents.[7] In addition, such action, while humanitarian and philanthropic, is economic in the highest degree. It is impossible to appraise the value of rational supervision of this character at an early age, not only in instances of tuberculosis, but also in the case of all dependents, defectives, and delinquents. It is a rational prophylaxis, and if consistently applied would be of inestimable advantage.

In the case of children, systematic inspection, and the diffusion of accurate knowledge is of great importance. We have inspectors of different kind, we have schoolteachers, and we have the police. In large cities we have dispensaries for the poor, and throughout the world we have the medical profession and its members stand ever willing to give counsel

and advice, if need be, without cost. Let everybody know about tuberculosis, and appreciate the fact that debility and unhealthful surroundings are predisposing causes. Let the schoolteacher view with suspicion the poorly nourished child. Let the factory inspector, who makes sure that no child is employed under legal age, also take note of the health of the children, and the sanitary environments of the factory or shop. Let the police officer on his beat observe the conditions of the residents of his district, and let him report what he finds. The weak, sickly child is in danger. The anæmic child is a candidate for tuberculosis. Deficient hygiene and insufficient and improper nourishment favor the development of future dependents upon the State. Education must not be sought to the injury of any child's health. It is better to do without schooling than to impair the child's constitution.

Above all others, parents should realize the possibilities in reference to their children. They should understand what constitutes hygiene, and must know that many of the luxuries with which they surround their children are often detrimental and dangerous. The child is essentially a young animal, and should be fed and cared for at least with the same consideration that farmers bestow upon their stock. The question should not be raised if a certain article of diet will hurt the child, but the parent should consider if it will do him any good. The mistake should not be made of attempting to "harden" the child by submitting him to undue exposure, but the value of pure air and sunshine should be appreciated. Above all the physician should be consulted while the child is well. Judicious professional advice, taking cognizance of all surroundings and realizing all possibilities, is of importance in directing the daily life of the child, so that any developmental error may receive timely attention, and any faulty method which interferes with the child's well-being may be corrected.

Philanthropy does much for the care of the children of the poor. In providing country outings, fresh air, sanitaria, and the crèche, there is a consistent attempt to improve conditions. Moreover, it must be understood that pulmonary tuberculosis is not the only form of the disease. In children especially the bones or the abdominal viscera may be infected. The dispensaries nad hospitals of our larger cities care for these cases, but almost always ignorance is responsible for unfortunate delay in providing proper treatment in time. The public should know regarding manifestations of tuberculosis other than pulmonary.

Where the adult is concerned, a new duty arises. Publicity has now other facts to include in its dissemination of the truth regarding tuberculosis, and other conditions to consider. The question of occupation, habit, temperament and environment must receive attention, and serious thought must be given to economic relationship in many ways. In addition to imparting information regarding the tubercle bacillus, the danger of infection, and the predisposing and fostering conditions that exist by virtue of unsanitary surroundings, we must also appreciate the value of consistent sanitation to the fullest extent, and in this appreciation we must combat poverty, immorality, and crime, and counteract, oftentimes, dependency and degeneracy. In a word, the publicity which is to be of real value must favor prosperity, and must try to solve the problems of an incomplete civilization.

It is impracticable in this connection even to mention the various methods in which an enlightened prophylactic endeavor will find expression. With the realization that all cosmic influences, all life processes, all economic relationships bear upon this important subject, comes the attempt at the improvement of all local conditions, and the amelioration of mankind in every way. In the effort to provide an abundant supply of pure air, an adequate supply of pure water, and a sufficient supply of pure food, the government—municipal, state or national—must act intelligently for the common good. The interests of capital must not be allowed to supersede the interests of the community. Building laws should exist and be enforced so that the disgraceful tenements of our slums become an impossibility. Indeed, it were well if the law regarding all dwellings, as is the case in Berlin, permitted the owner to build upon only two-thirds of his lot, and above all things, it were most desirable if existing laws regarding plumbing ventilation and other hygienic measures were not so often a dead letter. The airing of cities has not received sufficient attention nor has adequate provision been made for free parks. The value of trees, plants, and flowers as a means of purifying the air is not fully understood. A pure water supply and facilities for its use internally and externally must be provided. Food should be inspected and when found impure should not only be condemned, but destroyed. Moreover, the drainage of all dwellings, the cleaning of the streets, the removal of garbage, the abatement of the smoke nuisance, should receive more attention in a practical way commensurate with the importance of such matters, not alone for utilitarian reasons, but because we realize the relationship of public hygiene to the spread of tuberculosis.

The question of occupation, and regulation of shops and factories is of especial interest, for the danger of overcrowding amid unhygienic surroundings is known. Our public conveyances, our trolley cars and railroad trains must be inspected, and our sleeping cars should be disinfected at frequent intervals. Our prisons and jails are often a disgrace to our civilization, and our lodging houses are a very hot-bed of infection. In connection with every municipal institution of this character, there should be a disinfecting plant, similar to the étuves of Paris. The tramp who secures a night's lodging should start out in the morning with a clean body, and his clothing properly sterilized.

In the consideration of occupation and residence as a predisposing cause of tuberculosis, we are met by a sociological problem of the utmost importance. The man must live, he must support his family, by his work alone can he gain a livelihood. To remove him from his surroundings may mean to pauperize him as well as his family. Right here the situation must be faced, and there should be no compromise. If the environments are unhygienic, especially if the man is unhealthy or already infected, he must move, and some agency must see to it that neither he nor his family starve. The citizen is the State's most precious charge, and his welfare should be its most important care. He has a right to demand protection from disease, and provision must be made in case of illness—actual or threatened—as in other forms of dependency. With tuberculosis in question, there is the additional and selfish incentive to action, because the man becomes a source of danger to others. Moreover, we know that treatment—either prophylactic or therapeutic—to be of the greatest service, must be applied at the earliest moment possible.

The practical methods to be applied in these cases are easily understood, but difficult of application. The Bismarckian scheme of insurance, which provides indemnity against old age, accident, sickness, and death for all whose income does not exceed $500 a year, is a philanthropic effort, the efficacy of which

has been demonstrated.[8] The institution of *Kassen*, or clubs, in Germany, brings immense clinical experience to certain specialists, and enables them to teach practically in a manner nowhere else possible in the world, but the chief advantage of such a system of compulsory insurance is the facility with which the poor receive timely treatment, and suitable financial help, in case of need. Such a system of insurance finds a parallel in our industrial companies, which, in default of governmental decree, offer an opportunity for the workingman to protect himself and his family against disaster due to loss of wage. Publicity benefits humanity by directing attention to this possibility, and it is not improbable that in the future the State may find means to protect itself, in some satisfactory manner, against these charges on its bounty.

For the present, each community in some way must attempt the care of the consumptives, and in many instances an enlightened public sentiment provides help and food for the wage-earner, deprived temporarily by illness of his wage, and this assistance has extended, when necessary, to his family as well. The report of the committee on the prevention of tuberculosis of the charity organization society of New York[9] shows how efficiently combined effort may accomplish definite results. The personal hygiene of the consumptive and the danger from infection to himself and to others have been detailed by many writers ably and fully.[10] The success of institutional treatment in high altitudes, and at home, is fairly well understood. The fact that tuberculosis is a curable disease is giving energy to renewed effort. We are studying with care the relation of intemperance and venereal disease [11] to tuberculosis, and we begin to appreciate in this connection the value value of education regarding the use of alcohol and the important subject of sex relationship.

There is still much to learn, but the essential fact to remember is the necessity at present of disseminating the knowledge that we already have. We must force home the truth about tuberculosis so each may know of his personal danger. We must warn against predisposing causes, and, to guard against the spread of the disease as we would against a conflagration, we must give attention to every case of infection as we would put our foot on every spark. The study of preventive measures in tuberculosis demonstrates again the dependence of each man upon his brother man, and is an object lesson in altruism. The appeal for the rich to help the poor has a new significance, and a personal and selfish interest, when it is realized how the disease may extend from one to the other. The necessity and the possibility of eliminating tuberculosis should cause a public awakening to each citizen's responsibility. The dissemmination of knowledge founded on fact, a consistent humanitarianism, a combined effort, a glorious and successful result—all these are made possible by a well-advised and determined publicity.

SUDDEN DEATH, ESPECIALLY FROM EMBOLISM FOLLOWING SURGICAL INTERVENTION.

By BYRON ROBINSON, B.S., M.D.,
CHICAGO, ILL.

The disasters of surgery are amply numerous to maintain the operator's heart in a constant state of palpitation. The laudable pus of pre-antiseptic days, it is true, is largely disappearing, but in its place is recognized the uncontrollable embolus. At present it is impossible to write a paper approaching finality on the causes of sudden death, for they are frequently unknown—undemonstrated even with the addition of an autopsy. Perhaps the term "sudden death" should include cases in which the final issue occurs within half an hour after an attack. A condensed presentation of a few of the causes of sudden death as related to particular visceral tracts may prepare the way for a comprehensive view of death in general demonstrating that sudden death is intimately related to death from natural causes. In the causes of sudden death, it seems to me we must bear in mind the vegetative centers, which especially belong to the sympathetic nerve, particularly the vasomotor, circulatory, or cardiac center and the respiratory center—both located in the floor of the fourth ventricle. It may be noted that the circulatory and respiratory centers in man are well separated, as the circulation will proceed for some time (over an hour) with cessation of the respiratory center.

The *tractus vascularis* is responsible for the majority of sudden deaths—over 60 per cent. It is the apex of the vital tripod of life. The following are some of the causes of sudden death: (1) Embolus; (2) air in veins; (3) acute anæmia; (4) fatty cardiac degeneration; (5) destruction of the cardiac center; (6) rupture of vessels (aneurysm, apoplexy; (7) myocarditis; (8) syncope (insufficiency of the left segment of the heart), resulting from embolism of the coronary artery, leading to cardiac anæmia and eventually to cardiac paralysis; hence the sudden death is a natural one and may be really slow, yet to the observer it appears sudden; (9) defective valves; (10) endocarditis; (11) cardiac rupture; (12) angina.

The *tractus urinarius* accounts for many sudden deaths, perhaps next in order to that of the tractus vascularis. The factors of sudden death from the urinary tract are: Nephritis, uræmic convulsions, diabetic coma, renal embolus.

The *tractus respiratorius* presents the following well-known factors to account for sudden death: (1) Pulmonary embolus; (2) obstruction of the trachæ (asphyxia); (3) pleuritic effusion; (4) chronic (latent) pneumonia; (5) œdema (pulmonary, laryngeal); (6) laryngysmus stridulus; (7) destruction or paralysis of the respiratory center, (8) obesity; (9) pressure on the oblongata, asphyxia (accumulation of blood in the left segment of the heart and in the lungs), asthma; (10) congestion; (11) apoplexy; (12) emphysema; (13) hæmoptosis.

The *tractus nervosus* is overrated as a factor in

sudden deaths. Perhaps less than 10 per cent. of sudden deaths are due to the nervous system. In sudden death certain visceral spasms must be observed, including death within the function of the sympathetic nerves. John Hunter died within a few minutes during a fit of anger. A slight shock, blow, or overexertion in a weak, exhausted person may result in sudden death—this would, however, be among the natural causes of death. The following factors in sudden death from the nervous system may be recognized: (1) Exhaustion (latent, chronic, or continued infection, overexertion); (2) cardiac paralysis (diphtheria, infection); (3) infection (diphtheria, streptococcus, etc.); (4) vagus inflammation; (5) meningitis (latent or chronic); (6) convulsions; (7) shock; (8) spasm; (9) joy, grief, anger, emotion, fright (icterus); (10) trauma on the abdominal brain, inducing reflex action in distant organs, as a blow on the epigastrium; (11) epilepsy; (12) destruction of the respiratory or cardiac centers, cerebral hemorrhage, pressure on the medulla (as fracture); (13) cerebral congestion; (14) cerebral anæmia.

The *tractus intestinalis* accounts for a number of sudden deaths. The most typical example is that of intestinal perforation from typhoid fever (5 per cent.), when the patient is exhausted from defective nourishment and long-continued infection. Also the tractus intestinalis may be the seat of volvulus, invagination, or acute obstruction, inducing sudden death. Causes of sudden death may be found in the appendages of the tractus intestinalis, as the pancreas (necrosis), or liver (acute yellow liver atrophy).

The *tractus genitalis* accounts for a goodly number of sudden deaths. It is a tract of extensive venous supply and is peculiarily liable to infection—venous trombosis. The following are factors residing in the genital tract which account for sudden deaths: (1) Embolus (especially following parturition); (2) ruptured ectopic pregnancy, infection; (3) hemorrhage (hæmatocele, hæmatoma); (4) uterine invagination.

The *tractus lymphaticus* accounts for sudden death mainly in connection with other visceral tracts, as the tractus respiratorius (pleurisy) and tractus intestinalis (peritonitis). Also chronic (latent) infection with sudden renewed invasion of the process, as rupture of an absecess, or sudden extension of the infection with chill.

Toxic substances cause sudden death; such are alcohol, ptomains (canned goods), hydrolyanic acid (peaches), bacteria, metallic poisons (lead), and inorganic compounds. With a colleague I performed an autopsy on a man who died suddenly shortly after entering jail. Careful macroscopic autopsy revealed no cause of death—only a slight gastritis existed. I remembered the features of the dead man as one who called at my office some time previously and asked me what was the fatal dose of potassium cyanide. This lent a clue, and on search a bottle was found on his person containing a fluid which proved to be potassium cyanide. The sheriff placed a drop of the fluid on a cat's tongue, and the animal died in about one minute. The poison cleared the mystery of sudden death.

In many patients there are pathological lesions (inflammatory or degenerative chronic, latent, suppurative) in the heart, arteries, or veins. These foci become the location of thrombi, which may dissolve, break up and float in the blood channels to the lung, kidney, spleen, liver, brain, and the serous membrane, as emboli. The thrombus is doubtless many times performed at the time the surgical procedure occurs. The patient may possess an altered state of blood favoring thrombosis, and eventually embolism. The cause of the sudden distribution of the embolus is in general some extra exertion or bodily trauma.

The general distribution of embolism following surgical operations is relatively: (1) Pulmonary, 70 per cent.; (2) renal, 12 per cent.; (3) splenic, 8 per cent.; (4) hepatic, 5 per cent.; (5) cerebral, 4 per cent.; (6) the serous membranes (pleura, peritoneum and joints), 30 per cent.

The embolus exists in two states, *viz.*, aseptic and septic.

Aseptic embolus damages chiefly by mechanical conditions, compromising function, respiration, circulation of blood, and lymph, renal secretion and nutrition, and injuring the peripheral nerves. An example of the aseptic embolus is seen in the sudden death following parturition due to an embolus from the placental site. The puerperal patient should be viewed as a wounded person.

Septic embolus damages not only by mechanical, but by bacterial conditions—infective, toxinic and suppurative processes. Death from embolus is more frequent than is noted by physicians who do no personal autopsies. Post mortems are very instructive in cases of sudden death, though not always revealing the cause of death. Large numbers of sudden deaths following operations on the peritoneum are due to embolus.

A brief narration of a number of sudden deaths chiefly following surgical operations, especially those involving the peritoneum, will emphasize the fact that embolus occupies a high place as a cause of death during surgical interventions.

Case I.—At midnight I performed a herniotomy on account of a forty-eight hour strangulation for Dr. Wm. Reese, of Dodgeville, Wisconsin. It was not a severe operation. The patient went to bed in a favorable condition. At five o'clock, five hours after the operation, the nurse was counting the pulse, which was 80 per minute, when in an instant the patient began to roll violently and rapidly in several directions, the pulse became irregular, and death occurred in two or three minutes. There must have been an embolus lodged in the region of the cardiac and respiratory centers (in the floor of the fourth ventricle), for both ceased to act within two minutes after the attack.

Case II.—Seventeen days subseqpent to performing vaginal hysterectomy, I was examining a patient to test for sciatica. I flexed the thigh on the abdomen and the leg on the thigh, when I suddenly forced the leg in extension. There was no pain. In about three minutes later the patient screamed with pain and struggled for breath. In a few minutes more she became slightly cyanosed, and died in 47 minutes deeply cyanosed and struggling for breath. By much persuasion I secured a postmortem examination, which demonstrated that the patient succumbed to repeated showers of pulmonary emboli from a thrombophlebitic left ovarian vein. The pulmonary artery and its branches were almost occluded with elongated spindle-shaped blood clots. The pulmonary artery became gradually obstructed and the patient died of asphyxia. It was the last floating embolus or the aggregation of the floating emboli obstinating the pulmonary vein that killed.

Case III.—Dr. Lucy Waite had under her charge in the hospital a patient who had several chills during the week. Dr. Waite suspected abortion, and dilated the uterine cervix under an anæsthetic. No curettage was performed, as the endometrium was smooth. The patient had a few light chills during the few subsequent days, and finally a profound chill, dying an hour later. Dr. Waite diagnosed pulmo-

nary embolus. She secured an autopsy under considerable opposition. I performed the post-mortem examination, and found the pulmonary artery almost entirely obstructed by emboli. I think the *exitus lethalis* was induced by a long spindle-shaped embolus, which, while floating in the blood current of the pulmonary artery, became rolled on itself, obstructing the blood channel. The source of the pulmonary emboli was the left ovarian vein, which was thrombosed—an old thrombophlebitis. The patient died from asphyxia.

Case IV.—I was called once to a distant city to consult in the case of a physician's wife, who was suffering from an abortion. I diagnosed metastatic embolic pneumonia with extensive pleuritic effusion. I aspirated several ounces of fluid from the pleura with but slight inconvenience to the patient. Three hours later the patient died suddenly. The respiration ceased at once. She was dead in about one minute after the attack. Such condition must be due to an embolus lodged in the respiratory center; however, the emboli may have been multiple, as the nurse reported that the heart ceased almost at the exact time as the respiration. The emboli may have been carried to the cardiac center. Preceding death a slight, but distinct, convulsion was visible in the ocular, facial, and neck muscles. I should judge that this was a convulsion of anæmia similar to the anæmic convulsion of a dying steer from hemorrhage. Autopsy generally demonstrates that such septic patients possessing thrombophlebitis suffer from repeated showers of emboli, and it is the final accumulation that kills.

Case V.—Some time ago I operated for Dr. Arthur McNeal on a patient for suppurating appendicitis, twenty hours subsequent to the attack. At the operation the pulse was 100, respiration 24, and temperature 103°. The secretions from the wound presented chiefly the pneumococcus. The patient improved for forty-eight hours, when he became icteric, the color of a yellow pumpkin, that was a septic embolus carried to the liver through the mesenteric veins from the infected region of the appendix. The patient's pulse, temperature, and respiration indicated a serious condition; however, the serious state almost completely disappeared by the sixth day after the appendicectomy. At the end of the sixth day the respiration suddenly, within an hour, rose to 48 per minute, the temperature became 104° per rectum, the pulse increased to 116 per minute. In ten hours later, more than half of the distal left lung was not functionating. He had a pulmonary embolus in the left lung. The patient's life hung in the balance for three days, when he slowly improved. Five weeks after the operation the patient breathed twenty-four times a minute, if quite quiet, but, if slight causes of excitement arose, his respirations continued at thirty per minute. Three months after the operation the patient gained some twenty pounds.

Case VI.—I once helped my assistant, Dr. Wm. E. Holland, to perform a hemorrhoidal operation. The patient became ill on the second day with embolic symptoms. By the fifth day following the operation the patient was suffering from fatal septic embolic pneumonia, and almost the whole body was bedecked with smaller and larger yellow septic embolic abscesses pelechiæ. He died on the sixth day.

Case VII.—I assisted Dr. Lucy Waite in an operation for blind abscess in the rectal wall of a young woman. There existed an abscess in the wall of the rectum immediately proximal to the external anal muscles, perhaps the size of a plum. Dr. Waite performed incision of the rectal sphincter muscles and curetted the abscess wall. The patient recovered with no unfavorable symptoms until the fifth day, when a septic embolus was carried to the liver through the inferior mesenteric vein. The patient became intensely icteric, and died suddenly a few days later.

Case VIII.—I recently assisted Dr. Alice Conklin to operate for an umbilical hernia on a patient some thirty-eight years of age. The patient entered the hospital ward with a record showing no elevation of temperature. The second day of preparation the record showed a temperature of 99° per mouth. The third day of preparation the temperature chart showed 100°. At the end of seventy-two hours of preparation she was operated upon. The umbilical hernia was closed by a proximodistal overlapping of the abdominal wall, fixing in position by silver wire sutures. The operation was easily and well performed with little trauma. Twelve hours later the patient had a chill. Fifteen hours after the operation I was called in consultation, and found the temperature 104°, pulse 130, and respiration 50 per minute. The right lung was laboring under rasping difficulties. There was cyanosis. The pulse rapidly rose to an uncountable state; temperature to 105.6°; respirations to 60 per minute. She died about forty hours after the operation from pulmonary embolism, both mechanical and septic states causing death, as demonstrated by the cyanosis and viciously high temperature. Examination of the corpse, per rectum or per vaginam, did not reveal any palpable pathological lesion to account for the septic pulmonary embolus following an aseptic operation. There was evident an old pathological state of the *ligamentum latum sinistrum,* which might suggest a thrombophlebitic utero-ovarian vein, from which frequently emboli arise.

Case IX.—Some time ago I had a case of obstetrics in which the patient sat up on the ninth day. In a few minutes she became ill, and died within an hour. This was no doubt a pulmonary embolus, perhaps from the placental site. Numerous puerperal women die from pulmonary embolus fragmented from the placental site.

Case X.—Not long ago I operated *per vaginam* for tuberculosis of the genitals and pelvic peritoneum (as proved by the beautifully typical tuberculous giant cells seen microscopically). On the fourth day after the operation the patient became icteric, of a lemon color, but with slight rise of temperature, pulse, or respiration. Emboli may have floated to the lung, kidney, spleen, etc. However, I had insufficient evidence to diagnose any embolus except the non-fatal one to the liver.

Case XI.—I once helped at the autopsy of a man who died in fifteen minutes after an attack in which struggle for breath was the chief symptom. We found multiple pulmonary emboli; existus lethalis appeared to be due to a long, spindle-shaped embolus, which, while floating in the pulmonary blood current, had rolled on itself, causing practically complete obstruction of the pulmonary artery. No operation had been performed. The patient died of asphyxia.

Case XII.—A woman, aged nineteen, entered the hospital under the charge of Dr. Lucy Waite for the purpose of having an operation for goiter. She was in the hospital for a week, being prepared, when she was suddenly attacked with rapid respiration and high pulse. Dr. Waite diagnosed pulmonary embolus, and called Dr. John A. Robinson and myself in consultation. Dr. Waite's diagnosis of pulmonary embolus was confirmed. The patient died thirty-six hours after the attack. No operation had been performed. Cases XI. and XII. are examples which demonstrate that the lesion (in heart, artery,

or vein) of inflammatory or vascular degeneration was performed, antedating the entrance into the hospital.

Case XIII.—A woman, sixty years of age, came to me from an adjoining State. She had carcinoma of the right kidney, which was functionless. The left kidney functionated, producing about forty-five ounces daily. I performed nephrectomy. She progressed excellently until the sixty-seventh hour following the operation, when, while relating a home story to the nurse, suddenly her eyes rolled violently, and she died in two minutes. In this case an embolus must have floated to the cardiac or respiratory center, or both, as respiration and circulation ceased at once. The location must have been the floor of the fourth ventricle—a vegetative center. There was no struggle for breath, no irregularity of cardiac action—she became unconscious in one minute and life's action ceased the next minute. Preceding death was a slight, but distinct, convulsion, which must have been the convulsion due to the anæmia of some vital center.

Case XIV.—I once resected a rib in a case of six months' pleurisy. The man recovered excellently for some four days. As I sat on his bed he said: "I never felt better in my life." Suddenly his eyes moved violently (ocular muscular convulsions) and became set. The facial muscles, especially the masseters, became rigid, as well as those of the neck. He died in about two minutes. An embolus had floated to a vital center—cardiac or respiratory. Some vegetative center or center requisite to maintain life—in the floor of the fourth ventricle—had suddenly become deprived of blood. Death was preceded by a rapid, transitory, but distinct, convulsion.

Case XV.—Some five years ago I was called to a town in Iowa to operate for an alleged large abdominal tumor. On examining the case I found an immense pelvic abscess. Under anæsthesia I punctured the abscess *per vaginam* and allowed the six quarts of fluid pus and blood to evacuate slowly. The patient progressed excellently until the third day, when she died suddenly, in about two minutes, after an attack. This no doubt was due to an embolus lodged in some vegetative or vital center (floor of the fourth ventricle), as both cardiac and respiratory centers ceased to act simultaneously. Large pelvic abscesses are liable to induce thrombophlebitis in the pelvic veins, and especially the plexus pampiformis. When the abscess contents are evacuated, the walls contract and the thrombi in the veins are liable to become fragmented and dissolved, and to float through the venous channels.

Case XVI.—My colleague was called to consult in the case of the young child of a physician. The child had diphtheria. It died suddenly, in a twinkle. A post-mortem examination was held by a distinguished neurologist, who reported death due to an embolus in the floor of the fourth ventricle.

Case XVII.—Many years ago I was attending a ten-year-old boy afflicted with mild diphtheria. About the stage of the disease (tenth day), in which the family and myself considered the boy rapidly convalescing, he suddenly and somewhat mysteriously died. The heart suddenly assumed irregular and extremely weak contractions. In a few hours he was dead. This death was absolutely a cardiac manifestation, all other functions were secondary. He died of "paralysis of the heart." Doubtless the cardiac center was damaged, but with what? Toxins, an embolus, or myocarditis?

Case XVIII.—Some fifteen years ago I visited in a country place a patient afflicted with periodic attacks of asthma. When examining the patient he was perfectly comfortable; however, though a layman, he grew slightly excited in regard to the anatomicopathological conditions of the lung in asthma. I remarked to him that a discussion with him as to the pathology of asthma would be fruitless. I prescribed, but he did not take the medicine. As I walked to the front gate of the house the patient suddenly expired. In asthma the respiratory center is in a state of irregular function, a defective state, and since in man the circulatory and respiratory centers are closely associated functionally and physically, it is not strange that sudden invasion of the circulatory center occurs in asthma. In asthmatic cases with sudden death, not infrequent, the cardiac center is the factor at issue—not the pulmonary center. Some forms of asthma are septic. Could this have been an embolus attacking the cardiac center in the floor of the fourth ventricle?

To repeat: Sudden death has attracted the attention of physicians from high antiquity. It constitutes perhaps one per cent. of all deaths. Frequently no single lesion (physiological, anatomical, pathological) will explain the sudden death (as when it occurs from joy, grief, or anger). Sudden death is rarely due to a demonstrable localized lesion of the vital tripod (heart, lung, or brain). It is more likely to be the consequence of a series of complications. It follows chiefly diseases of the circulatory apparatus.

We are not always precisely informed as to the exact cause of sudden deaths. For example, a young girl had sudden abdominal pain a week previous to entering a hospital. During her eight days of illness she had abdominal tenderness, vomiting and constipation. On the eighth night of illness she awoke with pain, and while speaking turned pale and died suddenly—instantly. The autopsy demonstrated only a pinhole perforation on the ventral wall of the stomach, surrounded by a circle of exudative peritonitis about an inch in diameter. The most plausible explanation of sudden death external to demonstrable physical facts is the sudden destruction of the function of the circulatory center (a vegetative center in the floor of the fourth ventricle). In man for sudden death, we must look to the circulatory center chiefly, as the respiratory center may cease acting long before death, while the circulatory center is definitely functionating. The heart may beat an hour after respiration has ceased, but the cessation of circulation results in instantaneous death. The death certificate of assigning as the cause "heart disease," through cloaking ignorance and fear of exposure, may, therefore, after all be approximately correct.

In operations on the peritoneum reflex irritation of the abdominal brain may check, shock, or paralyze the heart; or, in other words, produce constriction of the vessels of the medulla oblongata.

Perhaps most sudden deaths arise from embolus. The sudden death due to an embolus in a vegetative center, the floor of the fourth ventricle, is preceded by (anæmic) convulsions of the muscles of the face, eyes, and neck (similar to the convulsions of a steer slaughtered by bleeding). The death from embolus in the pulmonary artery is generally due to asphyxia. Embolus causes death (*a*) by anæmia of vital or vegetative centers (floor of the fourth ventricle); (*b*) by asphyxia, mechanical (in the pulmonary artery); (*c*) by infection, sepsis; (*d*) by destruction of parenchyma, infarcts, devitalizing the maximum power of the organs. An embolus in general is broken off from the local thrombus through trauma, extra bodily activity, or liquifaction of the thrombus. The chill following is the result of infectious distribution.

The myocardium may be the seat of a chronic (latent) fatty degeneration and under the strain of an anæsthetic, and the operation may become acutely diseased, ending in sudden death from cardiac paralysis.

Can sudden post-operative death (from embolism) be retarded? Patients about to be operated upon, especially when the peritoneum is to be opened, should have anatomical and physiological rest for from forty-eight to seventy-two hours, or more, according to the gravity preceding the operation in order to produce maximum visceral drainage, to avoid the fragmentation of any thrombus through the surgical or anæsthetic trauma and extra bodily effort, and also to allow acute inflammatory process to subside.

All abdominal surgeons of experience have observed the frequency of embolus following operations for appendicitis, hemorrhoids, and hernia (*tractus intestinalis*); operations for pelvic diseases, as ovariotomy, pyosalpinx, pelvic peritonitis (*tractus genitalis*); operations on the kidney, prostate, and bladder (*tractus urinarius*). The vast venous plexuses connected with the *tractus intestinalis, tractus genitalis* and *tractus urinarius* are prone to phlebitis and consequent thrombus, which may dissolve or become fragmented, becoming a floating embolus. Simple anatomical and physiological rest may avoid liquifaction or fragmenting of the thrombus.

The great essential in surgery is, first and last, diagnosis. The accurate diagnosis of any pathological lesion in heart, artery, or vein, suggests ample and proper time of preparation, especially for all surgical interventions on the abdominal organs closely related to the large plexuses of veins belonging to the systemic or portal systems where thrombotic veins may exist. The surgeon, as respects embolus, should be on his guard in operations for infected appendix, strangulated hernia, hemorrhoids, and infected pelvic organs. Most emboli appear to originate or to break off as a result of some bodily trauma, hence it is the duty of the surgeon to give the patient the benefit of all doubt by placing the patient in as perfect a condition of physiological and anatomical rest as possible several days previous to operation.

Ample and complete visceral drainage by means of water (better one-half physiological salt solution) is the first essential, not only to avoid shock in the operation, but for physiological and anatomical rest. The *tractus intestinalis* should be completely evacuated, a dozen movements, so that one can see the bile glistening in the stool. The *tractus urinarius* should be drained by drinking eight ounces of half decinormal salt solution every two hours for six times daily, which increases the quantity and clarifies the urine. With the *tractus urinarius* and *tractus intestinalis* drained to a maximum, the patient can be placed in the most perfect condition of physiological and anatomical rest, which is the safest condition for any surgical intervention. It is a prophylactic against embolism. Such a state withstands to the highest degree the trauma of anæsthesia, shock, peritonitis, infectious invasions, nephritis, pneumonia, and embolus.

The avoidable death is the black spot on the surgeon's escutcheon.

Action of the X-Ray in Cancer.—According to v. Bruns of Tubingen the action of the *x*-ray in cancer is simply an accessory to the mutually-occurring degeneration. Quoting Virchow, he explains that cancer is naturally of low vitality and self-destructive, and that could the formation of new nodules be combated, the condition would be self-curative.

THE TREATMENT OF DIGESTIVE DISORDERS.

By JAMES. W. HUNTER, Jr., M.A., M.D.,
NORFOLK, VA.

The methods at present so largely employed in the treatment of digestive disorders are so unsatisfactory in their general application and results, that it seems well to call the attention of the profession to another. I refer to a rational treatment. And, while it cannot be expected that a rational treatment will prove a panacea for all digestive ills, it will have a tendency to produce a number of permanent cures. Moreover, we may reasonably expect to conserve the forces of the human body, and, if we do no positive good, we shall, at least, do no positive harm.

An inability correctly to diagnose digestive affections, as well as a tendency to treat all cases of indigestion by a routine method, has led to a certain amount of neglect. The knowledge, moreover, that certain ferments will relieve a single attack has encouraged their use. But what is the effect upon the patient? Nature, finding that she has no longer to secrete ferments of her own, ceases to do so. The mucosa of the intestinal tract becomes inert; the glandular structures atrophy. Larger and larger doses are required to effect the same relief and in turn there results a chronic dyspepsia. And thus we maintain that no treatment, though affording a temporary relief, which causes a permanent injury is to be commended.

We should not be satisfied with the simple statement by the patient of the symptoms which distress him; a systematic enquiry into his heredity, habits, etc., as well as a physical examination, should always be made. The length of time employed in eating, the preparation of the food, the amount of eructation, whether there exist idiosyncrasies, pain in the precordial region, a palpitating heart, or a constipation, these questions must always be asked and their answers noted. For it is our endeavor, not so much to determine the distress itself, but, if possible, the underlying cause, and to remove it.

We should proceed to make a careful physical examination, observing the general state of health, especially if there be an anæmic or neurotic condition. We should likewise examine the conjunctivæ, gums, skin, facies, etc., also the reflexes. A knowledge of the condition of the lungs and particularly of the heart will also serve our purpose. The position of the latter whether compressed or not, as well as the existence of borborigmi, should be noted. And, lastly, the condition of the abdomen, if tympanitic or dull, and the relation of liver, kidneys, and spleen. It used to be thought that an enlargement of the tympanitic triangle indicated an enlargement of the stomach, but such a theory has long since been abandoned.

An examination of the mouth, teeth, and tongue should not be omitted. This done, we should, in doubtful cases, proceed to administer a test meal, and, upon its withdrawal note its amount, color, soam, reaction, quantity of free hydrochloric acid, and the presence of lactic acid. The sediment should be examined microscopically. The Boas-Opler bacillus, epithelial cells, sarcinæ, etc., will not be without significance. An examination also of the fæces will aid us.

Thus we have examined our patient. We are now prepared to differentiate the factor at fault, and, if possible, to correct it.

It will be well, at the very beginning of treatment, to render the patient's system as thoroughly clean as possible. Consequently, we shall administer a good cathartic (preferably a cholagogue such as

calomel or podophyllin), to be followed by a saline. Concretions of fæces, undigested and putrifying particles of food, cast-off epithelium, excess of gastric, intestinal, and biliary fluids, these will be removed, and the system rendered clean. Personally, I like a tablet containing a quarter of a grain each of aloin, cascarin, and podophyllin, and an eighth of a grain of extract of belladonna. One or two are given at bed time, and in the morning before breakfact, Rochelle salts ʒss, or solution of magnesium citrate, fʒiij to fʒvj.

But we can not be content with rendering the system clean; it must not be allowed to become dirty. Thus regular and systematic defecation should be encouraged, and, if necessary, laxatives must be administered. It should, however, be remembered (and that most distinctly) that the continued use of salines or of natural purgative waters does more harm than good. The system needs cleansing, but not purgation. The conservative forces of Nature must be excited to perform their function. If possible, laxative fruits should be eaten; an apple at bedtime, sweet oil in tablespoonful doses, or a plate of stewed prunes, will, if they do not distress, be productive of happy results. But if it becomes necessary to administer drugs, some preparation of cascara sagrada at night or phosphate of sodium in the early morning, is probably the best. The ordinary enemata should be discouraged, as their prolonged use inhibits rectal and sphincteric movements.

Recently, Murray, in writing of rectal constipation in women (Medical Record, August 6, 1904), recommends enemata of olive oil, especially when there has been some displacement of the rectovaginal septum. She advises an enema at bedtime of as much olive oil as can be retained, starting with a half cup, and increasing until three-fourths or even a full cup is reached. This is used every night for three weeks, then every other night for another three weeks, then gradually discontinued. The method has much to commend it, especially in anæmic individuals. It is harmless, and it seems to me well worthy of a trial.

The mouth requires constant attention. The teeth must be kept clean and rendered as efficient as possible. To this end, a dentist should be consulted, all cavities filled, and all missing teeth supplied. Nor should the gums, tongue, or mucous membrane be neglected. If they are at all foul (or in the popular phraseology, "taste bad"), they should receive a frequent cleansing with some mild antiseptic. I would suggest borax water (to which a little spirit of camphor may be added), Dobell's solution, one-quarter to one-half strength, or some of the various mixtures of the essential oils. All sores must be healed as rapidly as possible, due regard being made for their etiology.

Proper time must be given to meals, and the food should be thoroughly chewed. Not one or two bites, a mouthful of water, and a bolting, as is customary with some people, but a careful insalivation and reduction to a pulp. Indeed, the old saying of Mr. Gladstone, that he chewed his food once for every tooth, might reasonably be endorsed. Having dined, our patient must not return to work too soon, for, having prepared his food for Nature, he must give her a chance to act. A rest of from one-half to an hour after meals should in the majority of cases be rigidly required.

Of the food itself a great deal might be said. Briefly, our food must be of the best quality, free from any taint whatever, and carefully prepared. The greatest art exists in cooking; the food must be made as digestible and appetizing as possible. Nor should the capacity of the system be over-reached. Fried foods, gravies, too much tea or coffee, and an excess of sweets, as well as the so-called "French cookery," must be eschewed. The simpler the cooking the better. Meats are best prepared by broiling or roasting; pastry should be excluded. It is far better to suit the food to our patient's capabilities than to load him with enzymes to digest it.

In extreme cases recourse must be had to milk, raw eggs, broths, and beef juice. But I would explain that I do not refer to the various commercial articles. Beef juice is best prepared by toasting steak over a hot fire and pressing out the fluid with a lemon squeezer; or, adding cold water to the chopped meat in the proportion of one pint to one pound, and after an hour slowly heating the mixture, but never allowing the albumin to be precipitated. Boiling must be avoided. A little salt and pepper may be added as an appetizer. Thus prepared, we have a beef juice capable of assimilation and highly nutritious.

We must encourage Nature to restore our patient's health, and to this end we shall employ regular habits, moderate exercise, fresh air, sunlight, and rest. Tonics will accomplish much. Thus the various bitters will stimulate the gastric secretions. A glass of very mild sherry, tincture of nux vomica, mx to xv, fluid extract of taraxicum, ʒj, or the compound tincture of gentian or cinchona may be taken before meals. Iron is best given directly after meals, either as the freshly prepared Blaud's mass, or as the tincture of ferric chloride mxv to xxv. The so-called organic compounds of iron have no advantage over the official mixtures.

We shall thus compel Nature to do her own work, but we should also be careful that, in so doing, she shall cause as little distress as possible. It is far better to prevent symptoms than to cure them when they arise. The carminatives (especially the oil of peppermint) are excellent in a stomach distended by gas, but if we can anticipate this very production of gas, we shall indeed confer a boon upon our patient. This I have been fortunate in doing. The antacids act nicely, especially the bicarbonate of sodium or carbonate of magnesium. Either can be combined with an intestinal antiseptic and a mucous protective. A mixture of sodium bicarbonate, salol, and bismuth subcarbonate, aā gr.v., after meals, will be found most effective. But as this is constipating, I usually prescribe the phosphate of sodium, ʒss to j, before breakfast. For that condition combining acidity with chronic constipation, the old Roosevelt formula of rhubarb, sodium bicarbonate, ipecac, tincture of nux vomica, and oil of peppermint (though perhaps a "shotgun") produces an excellent result. The addition of the ipecac in doses of gr. ¼ seems to act as an intestinal irritant and to promote the pancreatic secretion.

Again it often happens that the stomach is unable to do its work for the simple reason that its secretion is not sufficiently acid. Hence it is well to administer the dilute hydrochloric or dilute nitrohydrochloric acid, mx to xxv, in a half glass of water an hour after meals. We should recall that pepsin is unable to digest food unless it be in an acid medium, but we should also remember that if we supply this acid, we should discourage its production by Nature. Thus we must wait until she has done her utmost, and then (but only then) assist her. An excellent treatment for that form of indigestion caused by a neurotic temperament (the so-called "nervous dyspepsia") will be the administration of whiskey and water, āa. fʒij to iij, a glass of sherry, or a little tincture of nuxvomica before meals, to be followed an hour after eating by the dilute acid.

So much for the prevention of digestive ills. The acute attack will often worry us. In this case, it will be well to administer a good carminative (such as sodium bicarbonate or oil of peppermint), and to follow it by a saline. If, however, the case demands a more rigid treatment, we must either use some mild emetic (preferably warm water and mustard) or pass the stomach tube. To this most patients object. A good substitute will be found in a mixture of hydrogen peroxide, ℥j, to a half glass of water, especially if encouraged by the insertion of the finger down the fauces. An enema containing glycerin or Rochelle salts will be found a useful adjunct in the treatment of intestinal colic, though in severe attacks morphine, hypodermically injected, will be required. And it may be added that after lavage, as when carminatives are used, a full dose of a saline will do no harm.

It is not the purpose of this paper to discuss the treatment of chronic gastritis, nor of the various affections to which the stomach and intestines are subject. Neither shall I attempt to burden you with a report of cases. Suffice it to say that in a series of eight I have been uniformly successful. One case, however, might be mentioned.

Mr. X., aged 30, had been suffering for some time with an affection, which his physician diagnosed as "nervous dyspepsia." He described himself as feeling weak; his food seemed to pass through him unchanged; alcohol alone afforded any relief. Inquiry elicited the fact that he had been treated with pepsin, pancreatin, strychnine, asafætida, and a natural purgative water, and had on one occasion been kept in bed for a week. This condition had lasted for some time, but there was no improvement. His conjunctivæ showed an anæmic condition; otherwise the physical examination was negative. The red blood count was normal though there was a reduction in the amount of hæmoglobin, it being about eighty-five per cent. He was placed upon Blaud's mass (freshly prepared) after meals, a mixture of dilute hydrochloric acid, tincture of nux vomica, and compound tincture of cinchona, an hour later, and salol and bromide of sodium between meals; at the same time he was directed to eat a number of raw eggs daily and to drink a great deal of milk. This was in addition to his regular food, which was to be limited to such articles as did not distress him. Within one week there was a marked improvement; within three, he was well. Several months have since elapsed, yet there has been no return of the trouble. This case I cite merely to show the effect of the enzyme treatment on the one hand and the rational on the other.

I would urge upon the profession the importance of a rigid examination of every case of indigestion. This done, we can make a correct diagnosis, and treat our patient intelligently. Do not try to do Nature's work; assist her in every legitimate way, but compel her to digest the food. She can do it far better than we. An instructor once advised me in these words: "Do not treat the indigestion; treat the cause." I would go further. Treat your patient, remove the cause of his complaint, prevent the disagreeable symptoms, improve his health, and he will regain his wonted strength.

216 Freemason Street.

A Comparison of Radium and X-Ray.—An important reason why radium will never come into general favor as a rival of the Finsen method and that of the *x*-ray is that its effects, as shown by histopathological investigations are altogether too superficial. It is also so rare that application to extended areas requires too much time.

INFECTIONS OF THE GALL-BLADDER.*

By THOMAS W. HARVEY, M.D.,
ORANGE, N. J.

On October 23 a patient was sent into the hospital with a history covering several years of repeated attacks of gallstone colic and jaundice. She was a married woman, a German of forty years, who had had several children and whose waist did not present a suggestion that she had ever been the victim of tight lacing. She had had at intervals of every few months attacks of pain in her upper abdomen of varying intensity. The last attack, from which she was still suffering, had been very severe; beginning with pain and vomiting, and accompanied by jaundice and chills and fever. Two days before her admission to the hospital she had been seized with a particularly severe pain and was found by her physician in a condition bordering on collapse.

She rallied from this condition, but when admitted to the ward was suffering from a great deal of pain which was paroxysmal in severity, but never absent. She had a rectal temperature of 100° and a pulse of over 100. She was moderately jaundiced, but her stools frequently showed the presence of bile, indicating that the obstruction was not constant. She was very sensitive over her right hypochondriac region, and the upper portion of the right rectus muscle was tense, so tense, indeed, that it was impossible to palpate the edge of the liver or make out the contour of the gall-bladder.

A diagnosis of cholecystitis, with a stone in the cystic or common duct, was suggested. A blood count of 8,000 leucocytes indicated that the cholecystitis could not be purulent. After the usual preparations the abdomen was incised through the right rectus muscle and the gall-bladder presented at the opening. It was inflamed and fully distended, but it was free from adhesions. The peritoneum in the neighborhood, over the liver, the omentum and parieties were injected and thickened. The hand passed into the abdomen, palpating the ducts, could feel a stone in the cystic duct, but none could be felt in the common duct.

After the abdomen was packed, the gall-bladder was incised and a quantity of glairy mucus was discharged. The last portion of this discharge was colored with bile. The gall-bladder walls were thickened and covered with blood-vessels, the mucosa was swollen and highly inflamed. Eight small stones in all were removed from the pelvis of the gall-bladder, among them being the one that had been in the cystic duct, and which was forced back into the bladder; another much smaller stone, which dropped down into the opening of the duct, was crushed during the manipulation for pushing it back into the gall-bladder. The bile began immediately to flow into the wound. The gall-bladder was then sutured to the superficial fascia and the rest of the wound closed.

The patient's convalescence has been without incident, her rectal temperature has kept below 100° and her pulse below 80. Bile escapes moderately; her stools were normal in color on the day after the operation and have remained so. She will make a complete recovery.

This is a typical picture of the milder form of gall-bladder infection resulting in the formation of gallstones with repeated infections. Sometimes there is complete obstruction and profound jaundice, due either to inflammation of the bile ducts or to the passage of a stone which in the attack gets caught in the common duct. The intermittence in the jaundice symptoms in this case suggested a stone in the

*Read before the Practitioners' Club, of Orange, N. J.

common duct which was bobbing back and forth like a ball valve; but evidently there had been a cholecystitis which caused enough secretion to flow into the gall-bladder to force a stone into the cystic duct, thus cutting off the drainage from the gall-bladder; distention of this organ ensued, which caused the pain, particularly the dull ache. There was catarrhal inflammation of the common duct, and the swelling of the mucosa prevented the free flow of bile into the duodenum and caused the jaundice. This catarrhal inflammation may have been the primary lesion in this case; an infection spreading from the duodenum and extending to the gall-bladder. At any rate drainage of the gall-bladder and emptying of the cystic duct allowed the bile, dammed up in the upper bile passages, to escape freely into the wound, and allowed the mucosa of the common duct to shrink up enough for bile to escape into the duodenum so freely that it is only during the intervals of digestion that the bile comes up through the gall-bladder into the wound, and this notably at night.

The present idea of the cause of gallstones is that they are due to bacterial infection of the gall-bladder. Such a cause has been demonstrated as possible by experiments on animals, in which it has been found that while sterile foreign bodies, even if irritating, do not give rise to formation of gallstones, the introduction of bacteria into the gall-bladder will be followed by the formation of calculi. Many bacteria have been found in the interior of gallstones, such as bacillus typhoides, bacillus communis coli, staphylococcus albus et aureus, streptococcus, and others.

We can all recall enough cases of jaundice, and of catarrhal inflammation of the biliary passages following epidemic influenza to be suspicious of that disease as a cause of cholecystitis. Typhoid fever is particularly liable to be followed by infections of the biliary passages. In these general diseases, it is said that by way of the portal vein large numbers of bacteria are carried to the liver and excreted into the biliary passages. Other infections undoubtedly creep up the bile passages from the duodenum.

The gallstones themselves are caused by the catarrhal inflammation and consequent desquamation of the mucosa, another important factor being stagnation of the bile. The result of autopsies has shown that the gallstones may be found in the gall-bladder without there having been symptoms enough during life to have suggested their presence. The inference is therefore plain enough that many infections of the gall-bladder are very slight in character and give rise to very few symptoms; in fact, are not severe enough to attract the attention of the patient or his attendants to the gall-bladder.

Kehr truly remarks that many cases of slight indisposition which are diagnosed as gastritis or bilious attacks, and we may add malaria, are very likely attacks of gall-bladder infection. It is not unusual to have a history of occasional attacks of discomfort and even severe cramps in the epigastrium, which are suddenly terminated by an attack of vomiting. The explanation of this symptom-complex is that a gall-bladder, the seat of gallstones, becomes infected, increased secretion causes distention of the gall-bladder and forces a stone into the pelvis of the gall-bladder, or into the opening of the cystic duct. The pain is due to the distention and contraction of the gall-bladder. Vomiting occurs. As a result there is relaxation, and the stone drops back into the gall-bladder. The secretion escapes, the tension is relieved and the attack is over.

It is generally believed that gallstone colic is as often due to the distention and contraction of the gall-bladder as to the passage of gallstones. From this we can understand those cases of cholecystitis and gallstones which have never given rise to attacks of jaundice. Such a case was that of an old lady whose gall-bladder was situated so low in the abdomen that the inflammation was ascribed to appendicitis, but who had a largely distended gall-bladder occupied by a solitary stone weighing one ounce.

Generally it is true that the more severe the infection the more severe the inflammation and the symptoms. As a result of the damming of the bile we will have swelling and tenderness of the liver. If we have a purulent cholecystitis it may result in empyema of the gall-bladder, or ulceration, in localized peritonitis, in atrophy of the gall-bladder, in cholangitis and abscess of the liver, in adhesions to different neighboring organs, in perforation into the peritonium, the stomach or the intestines, large or small, and if a stone is forced into and becomes lodged in the common duct we may have an acute or chronic pancreatitis, resulting from the obstruction occurring at the papilla of Vater, and of the extention of the infection into the pancreatic duct. Some authors attribute malignant disease of the biliary organs to preceding infections. I am disposed to consider such infection as one of the elements in the etiology of cirrhosis of the liver.

The symptoms of cholecystitis are pain, tenderness, nausea and vomiting, fever and chills, tumor at the end of the ninth rib and rigidity over the right rectus muscle. In this symptom complex jaundice is not mentioned, as it is not a symptom of a primary inflammation of the gall-bladder. It is, however, often present, owing to the accompanying inflammation of the bile ducts, or to their obstruction by stone. The pain in cholecystitis varies greatly in intensity and character. It may be simply a dull ache, or it may be the most severe spasmodic colic. Its location is to the right of the median line and the pain radiates to the right side, and to the right shoulder. "This variation in intensity is directly dependent upon the varying causes of the pain in gallstone diseases, which may be inflammation, distention, colic or spasm induced by a foreign body." (Musser.)

The tenderness is found over the gall-bladder and along the border of the ribs. When the gall-bladder is not near the surface, tenderness may be found by lifting the ribs and pressing down deep beneath the liver. (Murphy.) There is nothing characteristic about the nausea and vomiting; it is not a constant symptom. The fever and chills have many characteristics of intermittent fever, but there is no regularity in the periodicity. The tumor, which may be very large, as in hydrops, is often wanting when previous attacks have left the gall-bladder atrophied and shrunken. Tension or rigidity of the right rectus muscle is present when the inflamed gall-bladder is near the abdominal wall and when there is a localized peritonitis.

The hematology of gall-bladder disease is still practically an unexplored field. Beyond the fact that in simple infections, with serous exudate, there is no increase of the leucocytes, and that in purulent cholecystitis a high leucocyte count is often found, we have little data for assistance in diagnosis.

The passage of a gallstone, while always a subject of congratulation, is not conclusive that the storm is over or the danger is past. There usually are more than the one stone. These stones are stored up in the gall-bladder, and may keep up the trouble for a long time, or they may be quiescent for many months, but the infection of the gall-bladder is still present, and is liable to be a future source of danger to the patient.

We can, therefore, say that while we should not make our diagnosis depend on the visual evidence

of a stone in the dejections, so our prognosis should not be particularly affected by the same phenomenon.

The differential diagnosis of cholecystitis is important and frequently difficult. The mild cases particularly are difficult of recognition; a case of moderate severity is most likely to be mistaken for appendicitis. The severe forms will have so many accompanying disturbances, and lesions of the neighboring organs, that it may be difficult to arrive at a correct conclusion.

The mild forms of cholecystitis, when there is only a moderate amount of pain and little tenderness, with a low febrile movement, are generally diagnosed as acute indigestion; particularly will this be the case when the attack is terminated by vomiting. In these cases the inflammation will not have extended far enough to involve the surrounding peritoneum and the characteristic tension of the right rectus muscle will be missing. If the pain is particularly severe we will have to consider the diagnosis from ulcer of the stomach. The location of the pain will be of some assistance, but the time when the pain is felt is most important. The pain of ulcer of the stomach is induced by and follows soon after the introduction of food; the pain of cholecystitis is more likely to occur during the time when digestion is not going on, as at night.

The cases of moderate severity, when there is evidence of more extensive inflammation, we have to diagnose from acute appendicitis. The analogy between the two organs and their inflammations, and the results of their various diseases, is very close. They are both favorably situated to be invaded by bacteria, and while the appendix is more liable to stasis, ulceration and perforation as a result of infection, and the necessity for early surgical interference is more strikingly manifest, yet we have the same story of acute destructive local disease, and spreading general peritonitis from gall-bladder infection, as in appendicitis, and the secondary effects are even more serious.

In both organs there is the danger of repeated attacks, and in each instance the patient is carrying around a powder mine in his economy, only waiting for a suitable match to determine an explosion. In both cases we have the danger of serious secondary infections. In both cases early operation effects a certain and safe cure.

We are likely to be confused also by the fact that frequently both organs are found in each other's anatomical territory; the gall-bladder down near the umbilicus or the appendix up close to the liver. In the absence of such dislocation, the rigidity of the right rectus muscle is the best guide to the proper diagnosis, being above in cholecystitis, and below in appendicitis.

In those cases where there is very severe pain we have to differentiate from renal colic, intestinal colic, from perforations of the stomach or duodenum, from certain neuroses of the liver or stomach, the abdominal neuralgias of locomotor ataxia and from intestinal obstruction. Other conditions to be considered are: Cholangitis, which occasionally occurs without any accompanying cholecystitis; congestion and abscess of the liver, syphilis of the liver, subprenic abscess, diaphragmatic pleurisy, pneumonia and the pancreatic diseases. The many forms of new growths of the gall-bladder and the neighboring organs have to be excluded before a positive diagnosis can be decided upon. The history of having passed a gallstone is not conclusive evidence that the present attack is connected with the gall-bladder. A recent case seen with Dr. Siebert was found suffering from profound jaundice, while a history of the passage of gallstones suggested that obstruction of the common duct might be the cause of the jaundice. Three symptoms, however, lead us to make another diagnosis. The presence of ascites, the fact that the patient did not give a history of paroxysmal attacks of pain and the diminished area of liver dulness lead us to diagnose the case as one of cirrhosis of the liver. I am disposed to think that cirrhosis of the liver may be considered as one of the terminal effects of infection of the gall-bladder. If this is so, it will account for some cases of cirrhosis of the liver which have been observed in those who have always been temperate in their habits. I hope that in the discussion we will hear the description of just such a case and of the post-mortem examination which showed conditions suggesting such a possibility.

Treatment.—There is no doubt of the possibility of spontaneous cure. There is no doubt that latency is the rule, even when infection of the gall-bladder has gone on to the formation of gallstones. There is no doubt that occasionally one attack of gallstone colic may be cured by the expulsion of the stone, and the consequent reestablishment of the normal condition in the gall-bladder and the bile ducts. The same thing may occur after frequent attacks of gallstone colic and expulsions of gallstones, but this is good luck.

Even when complete obstruction occurs and persists, ulceration and perforation into the intestine may give free outlet to the bile and all the dangerous symptoms may subside. Even those who are subject to recurrent attacks may be kept in fair health and comparative security by careful attention to diet and to those remedies that are calculated to control catarrhal inflammations of the gastroenteric tract. There are, however, no specifics; there are no solvents of the gallstones. Infections of the gall-bladder are surgical diseases, and if we are to treat them rationally we must treat them surgically. This treatment consists of incision and drainage of the gall-bladder or in its complete extirpation.

It has always seemed plain enough that the function of the gall-bladder is to act as a reservoir for the surplus bile, where it is stored up during the intervals of digestion; a very useful organ for the animal or for the savage, who often can eat but once a day, or perhaps once in two days. But civilization with its frequent meals is putting the gall-bladder out of commission, although the modern club man, with his one meal a day, and who is evidently a reversion, is bringing it into fashion again.

When, therefore, we find an organ whose presence in the economy is not a necessity, whose primary diseases are mild and curable, but whose secondary diseases are so serious and fatal to the integrity of important organs, and even to the individual; moreover, when the organ in question can be attacked so successfully by the surgeon in the early stages of its diseases, the inference that we should sacrifice the organ early, when it has become the seat of infection, is very clear. If we should cure all our cases of cholecystitis by drainage or by excision of the gall-bladder, gallstones would disappear from the annals of surgery.

Women in Medicine.—The honor of granting the first degree in medicine to a woman is not at all recent. The University of Paris, nearly one hundred years ago, made Madame Boivin, the famous midwife, a doctor of medicine. She proved herself worthy of the degree not only practically but in a literary way, and besides membership in French and foreign scientific societies, she held an honorable position under the government as chief inspector of a home for convalescents. She died in 1841.—*Woman's Medical Journal.*

PNEUMONIA IN HIGH ALTITUDES.

SUMMARY OF ONE HUNDRED AND ONE CASES OF LOBAR PNEUMONIA TREATED AT THE AMERICAN HOSPITAL, MEXICO CITY, FROM 1890 TO 1904.

By ALBERT R. GOODMAN, M.D.,
MEXICO CITY, MEXICO.
SURGEON TO THE AMERICAN HOSPITAL.

While it has been a general belief that altitude has a direct influence on the frequency and mortality of acute lobar pneumonia, exactly to what extent such an influence may exist, and whether there is a definite ratio between altitude and frequency, or altitude and mortality, are still unsettled questions. In the hope of aiding in the solution of such a problem, the following statistics are put on record:

Mexico City is situated on an elevated plateau, almost completely surrounded by mountains; it thus lies in a basin, its altitude being 7,348 feet, while the surrounding mountain chains have a height of 9,000 to 10,500 feet. In general terms, its climate may be said to be temperate and equable with a definite "rainy" season from June 15 to September 15, and a definite "dry" season, more or less, from September 15 to June 15. According to statistics of the Board of Health, the highest death rate exists in May, just before the rains, with February and March close seconds. The "rainy" season is the healthy season; the "dry" season the unhealthy one. One notices the high altitude mainly in the sudden change in temperature, with the appearance and disappearance of the sun; there is almost no dawn nor twilight.

The American Hospital treats both "pay" and "free" patients, but, as in most similar institutions, those of the latter class predominate. The patients are largely, if not entirely, drawn from the American and British residents, with an occasional German. It is also to be remembered that the class of people which contributes largely to the "free" patients is derived in the main from a transient or floating population.

In 1890 there were 5 cases of pneumonia out of a whole of 116 hospital patients; in 1894, 4 out of 172; 1892, 3 out of 179; 1893, 7 out of 190; 1894, 6 out of 179; 1895, 4 out of 179; 1896, 4 out of 264; 1897, 7 out of 329; 1898, 10 out of 292; 1899, 14 out of 379; in 1900, 4 out of 361; in 1901, 6 out of 396; in 1902, 11 out of 476; in 1903, 7 out of 315; in 1904 (to October 1), 9 out of 340, giving a total of 101 cases of pneumonia out of 4,367 cases of disease treated in the hospital in fifteen years. Of these 101 patients, 91 were male and 10 female. The fact that the patients were recruited from a transient population probably had a direct influence upon the large preponderance of males.

Grouping the cases by months we find that there were in January, 11 cases; February, 14 cases; March, 18 cases; April, 15 cases; May, 11 cases; June, 10 cases, a total of 79 cases in the first six months. In July, 4 cases; August, 2 cases; September, 2 cases; October, 3 cases; November, 6 cases; December, 5 cases, a total of 22 cases in the second half of the year. A marked preponderance—3½ to 1—occurs then in the first six months of the year; *i. e.* before the rainy season; during the rains and directly afterwards the number is small.

The mortality of various years differs so greatly that I am inclined to believe that errors must have existed in the diagnosis or in the records. These patients were also treated by a number of physicians, another possible source of error. Since 1898, the records have been kept with more care than during the years previous. The hospital records give the following percentage mortality by years: In 1890, out of 5 cases treated there were no deaths; in 1891 the mortality in 4 cases was 25 per cent.; in 1892, 3 cases, 66 per cent.; in 1893, 7 cases, 28 per cent.; 1894, 6 cases, 16 per cent.; 1895, 4 cases, 25 per cent.; 1896, 4 cases, 25 per cent.; 1897, 7 cases, 14 per cent.; 1898, 10 cases, 50 per cent.; 1899, 14 cases, 50 per cent; 1900, 4 cases, 50 per cent.; 1901, 6 cases, 84 per cent.; 1902, 11 cases, 45 per cent.; 1903, 7 cases, 71 per cent.; 1904, 9 cases, 22 per cent. The average mortality for all cases during this time was 39.8 per cent. If we deduct 4 cases in which death occurred within 24 hours after entering the hospital, the patients probably being moribund when brought in, this mortality is 37.1 per cent.; of cases treated in 1898, *i. e.* since more accurate records were kept—61 cases in all—the mortality was 50.1 per cent.; of these four died within 24 hours after admission; the mortality of the remainder treated was 47.4. The average of these four mortality percentages is 43.5.

This, in my opinion, represents fairly accurately the actual mortality of pneumonia as existent in the hospital.

Medical Education in Japan.—Kakichi Mitsakuri states that the first western knowledge introduced into the Japanese empire was through a Dutch textbook of anatomy, which came into the hands of a Japanese physician about the year 1771. After years of study this physician and three of his friends published a good translation of this book. It had taught them that their former teaching had been wrong. On looking first at the illustrations in the book they dissected the body of a criminal in order to find out who was right, they or the teachings of the Dutch book. After the introduction of anatomy came chemistry, natural history, history, military tactics, etc. In 1868 the Imperial University was established. It had a four years' course, admitting one hundred students to each course. In the educational system of Japan there are three grades, the university, the professional school, and all the schools below that grade. The boy begins going to school at six years of age. In the high school one foreign language is studied, either English, French, or German being generally taken. Those who plan to become physicians also take German, for that is the medical language of Japan. All physicians in Japan speak German and many of them write it. The arrangement of the course is based on that of the German schools and at one time all of the professors were German. Now they are all Japanese, except two honorary members of the faculty. The subjects studied in the medical college are similar to those studied in American colleges. Attached to the university is a hospital, having about 400 beds. After the student receives his degree at the end of four years, he is allowed to practise without any further examination. But many students spend several more years at home and abroad in preparation for their life work. A number of easier schools have been established in Japan where students are allowed to go directly from high school. The Japanese language is used in these schools, but a very good class of physicians is turned out. The graduates of these professional schools are also allowed to practise without a State examination. There is a third class of students, who go through an irregular course of training. They are allowed to obtain a license by passing a State examination. The demand for physicians in Japan is not completely supplied, especially in the country districts, but this deficiency will be overcome in a few years.—*St. Louis Medical Review.*

Kerosene as a Culicicide.—There is no better larvicide than kerosene to keep down the number of mosquitos, but it does not kill all the adult insects that come to lay eggs on the surface of the water.—St. George Gray.

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 14, 1905.

REPORT OF THE SURGEON-GENERAL OF THE PUBLIC HEALTH AND MARINE-HOSPITAL SERVICE.

THIS report for the year 1904 has been issued in the form of a volume containing no less than 640 pages of reading matter and statistics. In addition to the cut and dried mass of figures, there is a quantity of information on affairs relating to medicine, disease, public health, and hygiene generally, as well as many original contributions by officers of the service.

During the year 840,714 immigrants were inspected by officers of the service to determine their physical fitness for admission as prescribed by the immigration laws. Attention is drawn to the fact that the class of immigrants now coming to this country is inferior both mentally and physically to that of former days, and that this inferiority tends to increase. A large number is now turned back either for further examination or for immediate deportation. Trachoma is the most prevalent disease among these aliens, although the liability to fines for carrying cases of this disease has compelled the steamship companies of Europe to exercise great care in the selection of their steerage passengers, and has checked the wholesale importation of individuals suffering from this infectious eye disease.

The report of the division of sanitary reports and statistics shows that during the six months ended December 31, 1903, smallpox was reported from 35 States, with a total of 13,739 cases and 606 deaths. During the six months ended June 30, 1904, smallpox was reported from 37 States and Territories, with a total of 11,367 cases and 512 deaths. Total for the year, 25,106 cases and 1,118 deaths. Total for the previous fiscal year, 1903, 42,590 cases and 1,642 deaths.

The Surgeon-General recommends the establishment of a leprosarium in the Continental United States, and it is suggested that in any legislation regarding leprosy there be included a provision for the detail of specially qualified officers in Hawaii for the purpose of making a thorough inquiry into the methods of cure. Plague, which has existed in San Francisco since March 6, 1900, though reported occasionally during the year, has steadily diminished. During the twelve months ended June 30, 1904, there were 24 cases and 23 deaths, but no cases has been reported since February last.

Nearly all the cases of yellow fever occurred near the Mexican border. A striking proof of the part played by mosquitos in the conveyance of this disease was given by the different conditions which prevailed in Mexico, where little anti-mosquito work was done, and in Texas directly across the river, where all anti-mosquito precautions were taken. In Nuevo Laredo, Mexico, 50 per cent. of the population contracted the disease, while in Laredo, Texas, only about 10 per cent. of the population were infected.

The work of conducting national quarantine for the exclusion of epidemic diseases has been carried on during the year at the forty national inspection and disinfection stations located upon the Atlantic, Gulf, and Pacific coasts of the United States. A total number of 7,021 vessels were inspected and 323 vessels disinfected before entry.

The service is working in cooperation with the Isthmian Canal Commission, especially so far as quarantine administration in the Canal zone is concerned. The Surgeon-General, however, expresses the hope that the maritime quarantine of that region will be conducted by the service, as it is in our other possessions. Surgeon-General Wyman goes on to say: "There is much dependence by the authorities of the Canal zone upon the work of the officers of the service in Chile, Peru, Ecuador, and Venezuela, as well as various West Indian and Central American ports, and it would maintain the harmony of the whole maritime quarantine service if some arrangement were made similar to that now existing in the Philippines and in Porto Rico and Hawaii."

The hygienic laboratory has done excellent work during the past year, including the examination of vaccines and serums under the provisions of an act approved July 1, 1902; experiments on car sanitation; examination of pathological specimens from various stations of the service; examination of cases of suspected plague at quarantine stations; and the investigation of various diseases, such as yellow fever, the malarial fevers, hookworm disease, tuberculosis, etc.

The result of the investigations made by Dr. Charles Wardell Stiles as to the "spotted fever" of Montana are embodied in a preliminary report. He states that he has been unable to confirm the hypothesis that this spotted fever is caused by a piroplasma, that it is transmitted by ticks, and that it originates in spermophiles (popularly known as "gophers"). He further states that his work is negative, so far as cause, treatment, and prevention are concerned. His results in testing the present theories regarding the disease were entirely of a destructive character.

The sanatorium for consumptives, Fort Stanton, New Mexico, is in a flourishing condition, the number of patients cared for continuing to increase. Three hundred and eighty-six patients have been treated during the year, exceeding the number for the previous year by 112. The results of treatment have been satisfactory.

This report is an extremely valuable document, and, as the Surgeon-General points out, shows that the service has fairly entered upon its functions as the national health organization.

Crawcraw in England.—Mr. Dencer Whittles, a lecturer on dental pathology at Birmingham University, is reported as saying that numerous cases of crawcraw have been introduced into that city. Several instances are described in which the infection appears to have been transmitted from one individual to another by kissing.

ENGLISH MEDICINE IN THE ANGLO-NORMAN PERIOD.

Dr. Joseph Frank Payne chose the above subject for the Fitz-Patrick Lectures for 1904, delivered by him on November 8 and 10, an abstract of which is given in the *British Medical Journal*, November 12. Dr. Payne points out that, contrary to the general belief, the Norman conquest did nothing to assist, though it did not arrest, the progress of medicine in England. Indeed, while the old English medical literature continued to be produced for nearly a century after the conquest, yet during this period no trace is found of any Anglo-Norman medical literature.

The Norman conquest, however, introduced considerable changes in the social position of medical practitioners. The Norman aristocracy, not speaking English, could not employ the old Saxon leeches, but sought the services of physicians of their own race. These physicians were exclusively clerical, and often rose to high office in the church. Many instances occurred under the Norman kings of Norman or French physicians who became the trusted advisers of kings and nobles, and were promoted to high rank. Thus the practice of the Saxon leeches must have been restricted to the lower and middle classes, who alone spoke English. Again, there was another marked difference between the old English and the Norman physicians—the latter were educated abroad, there being no regular school of medicine in England.

All physicians of whom anything is now known studied at Salerno, which at the time of the Norman conquest, like the other great European medical schools, had fallen under the influence of Arabian-Greek medicine. Arabian teachers in many respects were far in advance of the late Latin and Greek authors, on whom the Anglo-Saxons in the Dark Ages depended. A great merit of the Arabian physicians was that they banished the supernatural from medicine, and as their tenets prevailed, superstition disappeared from the practice of medicine.

The Arabians, likewise, introduced a knowledge of diseases hitherto unknown, as smallpox and measles, and gave a better account of some old diseases, as leprosy. They also brought in a far more extended knowledge of drugs and methods of pharmacy, in addition to distillation and other chemical processes. On the other hand, Arabian medicine had a somewhat unfavorable influence, in that its exponents were slaves to dogma in matters of science. The Mahommedans based their most fundamental beliefs on an infallible written dogma, and further, although they were averse to superstition, they were ardent partisans of astrology, and this pseudoscience, with most injurious results, was brought into the field of medicine. "Thus," says Dr. Payne, "for better or for worse, it was this Arabian modification of Greek medicine which ruled in Europe for centuries, and of this Gilbert was no mean exponent."

Dr. Payne then gives a lengthy sketch of Gilbert and the state of medical lore in his time. Gilbertus Anglicus, the first English physician to acquire a European reputation, was at Salerno and in the East about the end of the twelfth century, in the time of Richard Cœur de Lion and the third Crusade. Gilbert was a voluminous writer, and his works form an excellent presentment of the condition of medical knowledge in Europe in his day, and of the medical teaching at Salerno in particular. In the treatment of all diseases Gilbert attached great importance to diet. For drugs he employed, beside simples, a number of old compound medicines, called "antidotes." He mentions more than two hundred of these, giving their composition. Gilbert mentions a few empirica—that is, superstitious remedies and charms, but his general method of treatment was that of the modern masters. His observations on leprosy were very valuable and formed the basis of much of what was written on this subject by medieval authors. Dr. Payne says that his description of the external signs of leprosy was evidently from first-hand observation. He described very accurately the anesthesia and other symptoms accompanying what we now call leprous neuritis, and acutely distinguished this affection from paralysis.

Gilbert's description of smallpox and measles was, on the whole, the most valuable contribution to the subject of medieval times. Dr. Payne says that Gilbert was the first author to draw attention to contagion in smallpox. He was also the first writer to suggest the red light treatment of smallpox, which John of Gaddesden is said to have carried into practice successfully in the case of a royal prince.

The last part of Gilbert's book is devoted to the hygiene of travelers by land and sea, in which he airs some theories which have since been recognized as founded upon sound principles. In conclusion, Dr. Payne points out that Gilbert was an eclectic; he sought to unite the old teaching of the school of Salerno with the newer doctrines of the Arabian and revived Greek medicine.

It would appear, as we have already noted, that at the time of the Norman conquest the Normans themselves employed physicians speaking their own language, and that the Saxon leeches practised among their own countrymen, but that the Normans had little or no influence upon English medicine. When, however, the two races began to be fused, a school came into existence, the members of which gained their knowledge in Europe, being both of Norman and of English blood; of these Gilbert was a typical and the most celebrated representative.

VARIOLA HYBRIDA.

Dr. A. S. V. Mansfelde, of Ashland, Neb., read a paper on variola hybrida before the Nebraska State Medical Association, held at Omaha, May 3 to 5, 1904, published in the *Western Medical Review* for September, 1904, in which he took the view that the disease which has been so prevalent throughout the United States during recent years, and which is regarded as genuine smallpox by the majority of physicians—is in truth not true smallpox, but a hybrid form of the disease, hybridized in its seed, whether that be of vegetable or animal origin. Happel defines variola hybrida as a modification of smallpox, in which not the person, but the virus which produces the disease has undergone a vital change.

Dr. Mansfelde contends that the virus of variola hybrida produces a clinical picture sometimes entirely and often greatly differing from genuine smallpox, and its virus differs from that of the virus of

varioloid in that it reproduces its kind—a fixed subspecies seems to have been formed. The author bases his argument upon his observations that some at least of the eruptions of true smallpox pass through every phase of their well-known evolution, while the eruption in the disease termed by some "variola hybrida" resembles acne. The shot-like papules of the genuine disease are seldom witnessed, and when the vesicles appear they very often look more like those of chickenpox than of smallpox, and umbilication is not seen. Dr. Mansfelde further states that the temperature after the appearance of the eruption generally becomes normal and remains so; secondary fever is not noticed.

The question as to whether there is such a disease as hybrid smallpox is answered emphatically in the negative by the bulk of the medical profession. Indeed, when Dr. Happel read a paper before the American Medical Association in 1901 to the effect that variola hybrida was the affection from which so large a number of American citizens were suffering, his views met with little or no favorable response. A joint session of the sections on Practice of Medicine and Hygiene and Sanitary Science, at this meeting of the Association, passed the following resolution: "That the disease now prevailing extensively in the United States, and called in some instances pseudosmallpox, is genuine smallpox, and should be so treated with vaccination and quarantine by all health authorities."

The medical textbooks, too, are unanimous in describing several anomalous varieties of smallpox, and the medical writers in this country have, with scarcely an exception, regarded the disease which has prevailed so widely as smallpox in a form modified presumably by vaccination.

Although, however, the weight of medical opinion is adverse to the views promulgated by Drs. Happel, Mansfelde, and others, yet it cannot be denied that the matter is a legitimate one for discussion. All is by no means yet known of smallpox, and the ventilation of radical opinions is healthy, and tends in the direction of increasing our knowledge of this universal scourge.

The Wood Alcohol Question.

Progress is not always advantageous, and the refinements of modern life are often doubtful blessings. A conspicuous illustration of the untoward possibilities that may attend apparent victories of science, is found in the steadily increasing list of casualties reported since it has been found commercially feasible to deodorize and rectify methyl alcohol. As long as the wood alcohol of commerce was the vile-smelling nauseous, greenish liquid variously known as wood spirit, wood naphtha, pyroligneous spirit, etc., its many offensive qualities caused its use to be restricted to various legitimate manufacturing and other purposes, but in recent years it has appeared under new names, and in a more attractive guise. Deodorized and deprived of its disagreeable taste, it has been put on the market in new forms, highly recommended by its exploiters for many household purposes. Dr. Casey A. Wood, in an interesting discussion of the subject, in the *New York Medical Journal*, of January 7, 1905, points out the dangers attending the dissemination of this disguised poison, which now can be, and is, widely used to adulterate whiskey and other alcoholic beverages, witch hazel, bay rum, eau de cologne, Florida water, essences of all kinds, Jamaica ginger, extract of lemon, etc., and the various liniments, patent medicines, and domestic remedies, so appealing to a large fraction of the population. Dr. Wood says that already one hundred and fifty-eight authentic cases of blindness and one hundred and fifty-six deaths, due to wood alcohol, have been reported, and that there is every reason to believe that if the whole truth were known, the total number of cases would be largely increased, and the full number would exceed four hundred.

Steps are being taken to reduce the risk from this source. One suggestion is to have all wood alcohol preparations placed on the list of poisons. Another, made by Dr. Frank Buller, is that every package of wood alcohol should bear the warning, "this fluid, taken internally, is likely to produce blindness." Such a label might be even more effective than the legend "poison," because to most people the fear of blindness is more impressive than that of possible death. Dr. Wood says that no doubt this precaution would limit the dangers of serious poisoning from methylated preparations, but it is very doubtful whether it will be entirely effective. Either the manufacture and sale of "deodorized" or "purified" wood alcohol, he holds, should be absolutely prohibited, or, as in Germany and Great Britain, an untaxed ethyl alcohol should be allowed for use in the arts, or the methyl alcohol should be rendered undrinkable by the addition of some nauseous compound.

Glucose Enemas in Diabetes.

Some time ago, J. Arnheim published in the *Zeitschrift für diätetische und physikalische Therapie*, p. 75, 1904, the results of a series of investigations undertaken to determine the reaction of the metabolism of diabetic patients to carbohydrates administered in the form of enemata. The observation that absorption could take place in this way and be followed by appreciably better assimilation than when the food was taken by mouth, as well as that of the disappearance of acetone bodies from the urine, was not only interesting from the theoretical standpoint, but gave promise of some practical bearing. A similar series of investigations undertaken by Orlowski (appearing in the December issue of the same journal) while yielding results which in the main corroborate those obtained by Arnheim still render the practical utility of the method very doubtful. It was found that the rectal administration of glucose produced a much smaller increase in the glycosuria than when the same quantity was given by mouth, and in many instances the amount excreted in the urine was always followed by a prompt rise. Analysis of the feces showed that the amount of glucose absorbed was usually about 50 per cent. of that contained in the anema, and control tests demonstrated that it was extremely unlikely that this amount could be entirely accounted for by intestinal fermentation. The effect of the carbohydrate administered in this way seems to be very slight, however, in diminishing the amount of acetone and allied bodies in the urine, and it is this fact which detracts from the utility of the measure. When a state of acidosis demands prompt action glucose enemas are too uncertain in their effect to be of service, while for long-continued use their employment is attended with so much discomfort to the patient as to render the plan impracticable. The theoretical side of the question remains of much interest, however, and although slowness of absorption or bacterial action may partly explain the modification in the excretion of glucose introduced into the body in this way, there are probably other still unknown factors also at work.

Gonorrheal Pericarditis.

Dr. F. Huber read a paper on the above subject before the American Pediatric Society, published in the *Archives of Pediatrics* for December. With the disappearance of the old view that gonorrhea is merely a local disease, the question of general infection by this disease has been thoroughly investigated during the past few years, and it has been discovered that all the structures of the body may become involved. Dr. Huber points out that gonococci may reach distant organs or structures in one of two ways, either through the blood circulation or by means of the lymphatics. In general it is believed that arthritic processes, endocardial, myocardial, and pericardial affections, pleurisy, periostitis, and phlebitis, are caused by the gonococcus, the majority of the others by the toxins. In many instances, however, a mixed infection has occurred.

In the paper read by Dr. Huber a report is given of a case of probable gonorrheal pericarditis occurring in a child three and one-half years old, under the care of the late Dr. J. Berenson.

Pericarditis, the author says, though somewhat frequent, is rarely the only manifestation. The affection is generally benign, does not give rise to much discomfort, and may run its course without any manifest symptoms. Objectively, it may occur as a dry form or may be attended with exudation. In the first variety the pericardial friction sounds are distinctly heard, in the other case dullness exists with feeble heart sounds. The effusion is generally serous in character, but at times it may be hemorrhagic.

Beurman has reported a case in which pus was formed. Other instances are mentioned in which several serous surfaces were involved (meninges, pleura, etc.). It may be said that the diagnosis of gonorrheal pericarditis is by no means easy. Generally the rheumatic symptoms are misleading. There is little doubt that gonorrheal infection is responsible for many more diseases than is usually believed to be the case, mainly on account of the difficulties in the way of a correct diagnosis.

Statistics of the Japanese Naval Officers and Men Killed or Wounded in the Present War.

The *Sei-i-Kwai Medical Journal* of October 31 gives statistics of the Japanese naval officers and men killed or wounded in the present war.

According to the recent investigations of the Medical Department of the Imperial Japanese Navy the total number of killed or wounded up to the end of September amounted to 2,321 persons. Six hundred and fifty-five of these were slightly wounded, five hundred and fifty-six severely wounded, one thousand and twenty-two killed, and eighty-eight missing.

The loss of the medical staff in the present war up to the date above mentioned was six surgeons killed or drowned, one chief medical attendant killed or drowned, eight medical attendants killed or drowned, and four medical attendants wounded. Six surgeons were attacked by infectious diseases, two assistant surgeons by typhoid fever, and thirteen medical attendants by dysentery or typhoid fever. All these recovered, a sufficient proof that the Japanese naval medical department know how to treat these diseases when contracted, as well as to prevent their occurrence.

The war in the Far East has been pregnant with valuable lessons from a medical and surgical point of view, and the pity is that the United States Government at the outbreak of hostilities did not decide to dispatch medical naval and military attaches to the front. The knowledge thereby gained would have been extremely valuable.

To Poultice or Not to Poultice.

Linseed and linseed meal have been dropped from army medicines, and the army physicians have been notified that it is the opinion of the Surgeon General's office that poultices have no place in modern therapeutics, all the good results obtainable from them being gotten in a much more cleanly way by hot wet compresses. This question, upon which the Surgeon General's office has officially pronounced, is a debatable one, and as a matter of fact there are many in and out of the army who will believe that this is a litle hasty. There are conditions constantly arising in which nothing but a poultice will, in the opinion of many not very old practitioners, suffice. It is not uncleanly, if properly applied, and can be made antiseptic as well as aseptic; but hot wet compresses are often more difficult to apply, and even with the greatest care are apt to moisten the bed and cause more bother than they are worth. The prohibition of the time-honored linseed meal, the best material for poultices, seems to interfere with a method practised by a large number of physicians, who would be inclined to testify that without it our soldiers would not receive the best care. There is surely much to be said on both sides. The psychological effect at least of a poultice is entirely too great for a successful family physician to ignore, and why deprive the soldier of this old-fashioned comfort?

The Mode of Turning, in Walking, as a Diagnostic Sign.

In the *Journal of Nervous and Mental Diseases* for July, 1903, reference was made to a paper by von Schüller, in the *Neurologisches Centralblatt*, of January 16, 1903, in which it is said that an organic hemiplegic patient can walk sideways towards his paralyzed side with little or no difficulty, but on account of the spasticity and lengthening of the palsied leg he has much difficulty in walking sideways in the opposite direction, and must drag the paralyzed leg. It is also pointed out that the functional hemiplegic cannot walk towards the palsied side, but only towards the sound side.

Dr. Leonard Kidd, of London, has been making observations recently to test the truth of this statement, and has concluded that in cases of organic hemiplegia and spastic paraplegia fully 99 per cent. of the sufferers spontaneously turn to the spastic or more spastic side when told to walk to the end of the room, turn round, and come back. He has never seen a functional hemiplegic turn round to the affected side, consequently he regards Schüller's phenomenon as a diagnostic point of the highest importance.

Dr. Kidd enunciates the following propositions: (1) If a spastic hemiplegic or a spastic paraplegic turns round in walking to the affected or the more affected side, an organic lesion is present. (2) If he turns to the sound or less affected side, the case is one either of functional or of organic affection; if the latter, there will be no difficulty in deciding in its favor after a careful physical examination. Dr. Kidd further gives it as his opinion that Schüller's phenomenon may have a much wider range than that of hemiplegia, and that a more extended experience will very likely show that in cases of unilateral weakness of organic origin the patient usually turns to the weaker side. If extended observations verify this belief, a diagnostic point of some value in nervous diseases will have been determined.

News of the Week.

American Public Health Association.—The thirty-second annual meeting of this association was held this week, in Havana, Cuba, under the presidency of Dr. Carlos J. Finlay. At a meeting of the laboratory section on Monday, under the presidency of Dr. V. A. Moore, of Cornell University, discussions took place on the "Purification and Preservation of Water Supplies," and the "Disposal of Sewage and Industrial Wastes." Mr. G. W. Fuller, of New York, chairman of the Committee on Standard Methods of Water Analysis, submitted an elaborate report on the changes and improvements in the methods used in bacteriological tests of water. The address of the Chairman, Dr. Moore, was delivered, and then the election of officers was held with the following result: *Chairman,* Dr. W. H. Park, New York; *Vice-Chairman,* H. W. Clark, Boston; *Recorder,* Dr. H. D. Pease, Albany, N. Y. The first general meeting of the Association was held on Tuesday evening, when Dr. Finlay delivered his presidential address, which was devoted chiefly to the history of the study of yellow fever in Havana. The banishment of yellow fever from the city was, he said, the direct outcome of the work of two American commissions, the first that conducted by Sternberg a quarter of a century ago, the second under the lamented Reed, twenty years later. The latter decisively established the true etiology of yellow fever. Two of its members were themselves prostrated by the disease, and one, Dr. Jesse Lazear, died a martyr to scientific zeal. Dr. Finlay praised the work of Major Gorgas, chief health officer under Gen. Wood, who, adopting the commission's findings, succeeded within seven months in ridding Havana of this century-old endemic. With reference to the two cases of yellow fever last October in Santiago Province, Dr. Finlay said it was presumed that they were transmitted by mosquitos from a quarantined ship. These were the only fever cases since 1901.

At the conclusion of his address, Dr. Finlay received a warm ovation from the large audience present. Several speakers accorded him praise for the large share he had had in this work, and full credit was accorded him for the great scientific acumen which had led him to the discovery of the part played by the mosquito in transmitting yellow fever, which discovery had been so positively confirmed by later investigations.

A paper was read by Dr. C. A. Snodgrass describing the system of chemical purification of the water supply now in use in St. Louis. A paper by Dr. A. H. Doty, Health Officer of the Port of New York, who was not present, was read. Its subject was the use of "Sulphate of Copper in the Destruction of Mosquito Larvae." At the afternoon session Dr. Erastus Wilson, of Havana, read a paper on "Sanitary Conditions in Havana and the Necessity for their Improvement." Professor L. C. Robinson, of Brunswick, Me., read the report of the Committee on Disinfectants. "The Disinfection of School Books" was treated in a paer by Dr. Walter Green, Health Officer at Buffalo, N. Y. Dr. C. V. Chapin, Health Officer of Providence, R. I., read a paper on "Sources of Infection."

The banquet took place at the Tacon Theater on Wednesday evening. In responding to a toast to the United States Dr. William Bailey of Louisville, Ky., spoke of the work the American army surgeons had done in the sanitation of Cuba, and said this work was being continued by the efficient health officer of the island, Dr. Carlos J. Finlay.

The Governor and the State Hospitals.—In his message to the Legislation, Governor Higgins dwelt at some length upon the needs of the State hospitals and their administration. He approved of the centralization of the management, effected by his predecessor in office, as regards the financial control, and recommended that the control of all financial matters be left, as at present, in the hands of the State Commission in Lunacy, but that there should be provided for each hospital a board of managers in general charge, through the superintendent, of the internal affairs of the hospital. Referring to the present overcrowding of the State hospitals, the large increase in the number of the insane each year, and the expiration next September of the lease of the buildings now occupied by 1,200 patients in the Long Island State Hospital at Flatbush, he suggested an increase in the capacity of the hospitals already existing and the establishment of a new State hospital. He also recommended that suitable legislation be enacted to enable the State Board of Charities to transfer inmates from one charitable or reformatory institution to another, when it appeared that such transfer would be for the good of the person so transferred. Different classes of defectives, he said, should not be allowed to remain in the same institution if by a proper system of transfers they can be so distributed as to receive the best and most scientific care.

The Harvard Cancer Commission.—The commission appointed by Harvard University, under the terms of the bequest of $100,000 by Mrs. Caroline Brewer Croft, to study cancer has prepared a report of its labors during the past four years. This report, which is now in the hands of the printer, will, if the advance statements of its contents are correct, contain little that is new. Its conclusions are said to be that cancer is neither hereditary nor contagious, that is is not of parasitic origin, and that excision is the only cure except in the case of certain superficial growths which may be cured by radiotherapy.

War on the Yellow Fever Mosquito in Rio de Janeiro.—A translation issued by the Liverpool School of Tropical Medicine of a part of the report of the preliminary yellow fever expedition of the Hamburg Tropical School shows that the authorities in Rio de Janeiro are alive to the fact that yellow fever is caused by mosquitos, and are determined to emulate the feat of the Americans in Cuba by stamping it out. Their antimosquito measures follow the American lines very closely. They include, for example, the disinfection, by pyrethrum, of houses where cases have occurred, the wiring of windows to prevent mosquitos getting in to bite patients suffering from the disease, and the organized employment of 2,000 men to exterminate the insects as far as possible throughout the town. One large source of mosquitos is found in the rain-water drains which form a vast network of pipes close under the surface of the streets; for these the Clayton apparatus comes in very handily. All outlets being covered by mosquito netting, the system is then divided into sections and the gas blown through, rats as well as mosquitos being exterminated. It is to be hoped that this enlightened policy will bear fruit, and be another lesson to the world at large demonstrating how much can be done in mosquito extermination.—*British Medical Journal.*

The Fifteenth International Medical Congress.—We have received the fourth number of the official journal of this Congress which is to be held at Lisbon on April 19-26, 1906. The secretary reports that the titles of 188 contributions have already been received on subjects officially announced for set dis-

cussion, in addition to a number of voluntary communications on other subjects. The twelfth section has been divided into two subsections—one on diseases of the nose, throat, and ear, and the other on stomatology.

Increase in the Army Medical Corps.—President Roosevelt has sent a message to Congress urging the passage of the bill, now before that body, for the reorganization of the medical corps of the army. He says he is satisfied that the medical corps is much too small for the needs of the present army, and therefore very much too small for its successful expansion in time of war to meet the needs of an enlarged army, and, in addition, to furnish the volunteer service a certain number of officers trained in medical administration. "If the medical department is left as it is no amount of wisdom or efficiency in its administration would prevent a complete breakdown in the event of a serious war."

The Uncertainties of Sea Travel.—The delegates to the Pan-American Congress at Panama who went by the steamer *Athos* from Baltimore had a sail and nothing else, for they did not arrive at Colon until last Friday, the day the Congress closed. The steamer was delayed a couple of days in Chesapeake Bay by a heavy fog, and lost another day on the way to Colon. There were thirty-eight would-be members of the Congress on board.

Yellow Fever at Panama.—Some apprehension has been caused by exaggerated reports of a yellow-fever outbreak at Panama. According to the report of the Public Health and Marine Hospital Service, however, there were but three cases of this disease at Panama between December 1 and 21, and at Colon there had been no cases since November 9.

War on Spitters.—Ten well-dressed individuals claiming to be business men were arrested in one day last week for spitting in the City Hall station of the subway. The magistrate at the Tombs police court fined them two dollars each. All offenders in this direction are not so fortunate in having the sum necessary to pay their fine, and must serve it out in jail. The wardens of some of the police court prisons say that they have more prisoners now serving time for spitting on elevated and subway station platforms than for any other crime. The recent efforts of the municipal authorities to suppress that habit has rounded up a lot of culprits. In some of the police courts nearly half a dozen are dealt with daily.

Typhoid Fever Diminished by Water-Filtration.—The prevalence of typhoid fever in those wards of the City of Philadelphia supplied with filtered water was in the year 1904 diminished 59.6% in a population of 100,000, as compared with the number of cases in the district supplied with unfiltered water.

Vital Statistics of Philadelphia.—For the week ended January 7 there were reported to the Philadelphia Bureau of Health 478 deaths, as compared with 497 for the preceding week and 656 for the corresponding week of the previous year. The largest number of deaths due to individual causes were as follows: Pulmonary tuberculosis 64; heart-disease 60, pneumonia 43 (not including bronchopneumonia 19 and congestion of the lungs 10), nephritis 39, apoplexy 19, old age 15.

Evanston, Ills., is one of the healthiest cities in the county, according to the figures of the health department of this suburb of Chicago. There were 201 deaths in the city last year out of a population of 23,000, or 8.8 deaths per thousand. The year before there were 212 deaths, or 10 per thousand.

Dr. Edward S. Peck, after an uninterrupted service of over twenty-five years, has resigned the position of Visiting Ophthalmologist to the City Hospital, Blackwell's Island. With one exception this is the longest term of service in connection with the hospital.

Dr. Oliver P. Coe has been appointed Deputy Coroner of Hamilton County, Ohio, by the Coroner-elect Dr. Otis L. Cameron. His salary will be $1,500, and term of service two years. Dr. Coe was formerly interne and later receiving physician at the Cincinnati Hospital.

College of Physicians of Philadelphia.—At a stated meeting held January 4, Dr. James M. Anders read a memoir of the late Dr. F. Savary Pearce. The President read his annual address, and the following officers were elected for the ensuing year: *President,* Dr. Arthur V. Meigs; *Vice-President,* Dr. James Tyson; *Secretary,* Dr. Thomas R. Neilson; *Treasurer,* Dr. Richard H. Harte; *Honorary Librarian,* Dr. Frederick P. Henry.

St. Louis Medical Society.—At the annual meeting of this society, held December 17, 1904, the following officers were elected for the year 1905: *President,* Dr. Frank L. Henderson; *Vice-President,* Dr. John C. Morfit; *Recording Secretary,* Dr. Thomas A. Hopkins; *Corresponding Secretary,* Dr. Chas. J. Orr; *Treasurer,* Dr. R. M. King.

Pennsylvania State Medical Examinations.—As a result of the recent examinations for license to practice medicine in the State of Pennsylvania 87 of the applicants passed successfully, while 39 failed to obtain the required average.

Improvement in Health of Chicago.—As a result of the intercepting sewer system in Chicago, the water from all tunnels has been found by rigid tests, made by the City Health Department Laboratory, to be as good as the samples taken 12 miles from shore, which is the department standard of "safety." The good results of this are seen in the lowest typhoid death rate, in 1904, in the history of Chicago. The reduction of mortality among children during 1904 was largely due to the improved quality of the milk supply, caused by the work of the department, aided by various volunteer agencies.

New York Polyclinic Medical School and Hospital.—The President of the Faculty of the New York Polyclinic Medical School and Hospital gave a reception on December 20 to celebrate the event of the liquidation of a second mortgage of about $40,000, which was accomplished by the personal donations of the members of the staff. This action was applauded by a member of the Board of Trustees in a material way by a personal donation of $20,000 to the new building fund.

The Sanitation of Cuba.—The Cuban Congress, which resumed its services on January 9, has passed the bill appropriating $326,000 for the immediate sanitation of the cities of the island. The Senate's special Committee on Sanitation recommended measures granting all municipalities $2.16 2-3 per inhabitant for city cleaning and sanitation, with an additional ten or twenty per cent. for the larger towns, according to population and importance. The appropriation bill was passed by the House by a vote of 23 to 15, and the recommendation of the Senate Committee for an apportionment to the several cities was informally approved.

Hospital News.—*The American Oncologic Hospital* in Philadelphia was formally opened with appropriate ceremonies on January 4. The hospital is in the old Howell mansion, Forty-fifth and Chestnut streets, and contains provision for twenty-four and assistant attending surgeon at the Women's

patients. The attending surgeons are Drs. Addinell Hewson, G. Betton Massey, and Howard R. Swayne, and the attending physician is Dr. Boardman Reed. The address at the opening exercises was delivered by Dr. G. Betton Massey who explained that the purpose for which the hospital was established was not only to treat sufferers from malignant disease, but to diffuse through the public the fact that cancer is a purely local disease and to encourage early application for treatment, and also to engage in a scientific research into the causation of cancer and kindred studies. Special facilities will be provided for the cataphoric method of treatment and for radiotherapy without neglect of the old and well-established surgical procedures in suitable cases.

The Cincinnati Hospital.—The Board of Public Service of Cincinnati has, by a vote of three to one, decided to build the new hospital on the Hill Top site away from the smoke and dirt of the business portion of the city. They also decided on the pavilion plan presented by the commission. The present City Hospital will be abandoned.

Ohio State Hospital for the Insane.—The commission chosen to select a site for this new Hospital have unanimously selected Lima, Ohio. The farm chosen about one mile north of the city contains 620 acres.

Nursery and Child's Hospital.—The annual Charity Ball to be given at the Waldorf-Astoria on February 2, for the benefit of the Nursery and Child's Hospital.

Gift to a London Charity.—The King's Hospital Fund has received as a New Year's gift $1,000,000, in securities yielding an annual income of $55,000, Lord Mountstephen, formerly president of the Canadian Pacific Railroad, is the donor.

Buildings at Cook County (Ill.) Hospital and Dunning Institutions.—The new buildings at these institutions increase the capacity of Cook County Hospital more than one-third, and at Dunning more than one-quarter. These buildings are nearly completed. They comprise cottages for consumptives, contagious diseases hospital, children's hospital, three cottages for insane, farm ward for insane, and pavilion (3 cottages) for insane. The only unfinished ones are the pavilion for the insane at Dunning, and the Children's hospital at Cook County Hospital, but these will soon be ready for service. The old hospital for consumptives at Dunning has been remodeled into a splendid hospital for the physically sick insane. The County has also erected at the Dunning Institutions a morgue and pathological building.

Sinclair Tousey Memorial Bed.—Benjamin Tousey of Syracuse, N. Y., has donated the sum of $5,000 to the Hospital of the University of Pennsylvania as an endowment for a free bed for the use of employees of the Central News Company and to be known as the "Sinclair Tousey Memorial Bed."

Obituary Notes.—Dr. CHURCHILL CARMALT of this city died of grippal pneumonia on January 8, after an illness of only three days, at the age of 39 years. He was born in Susquehanna county, Pennsylvania, and was educated at Harvard University, from which he was graduated fourth in his class in 1887. He received his medical education at the College of Physicians and Surgeons, from which he was graduated in 1891. He was an interne at the New York Hospital and was the first house-surgeon at the Hudson Street House of Relief of this hospital. At the time of his death he was demonstrator of anatomy at the College of Physicians and Surgeons, attending surgeon at the Lying-In Hospital, Hospital. All exercises at the College of Physicians and Surgeons were suspended on Tuesday of this week, in honor of his memory.

Dr. FREDERICK H. GRIFFIN died at Philadelphia on January 1 at the age of 47 years. He was graduated from the Medical Department of the University of Pennsylvania in the class of 1880.

Dr. BRYSON C. PENNINGTON died at Atlantic City, N. J., on January 1 at the age of 46 years. He was graduated from Jefferson Medical College in the class of 1881.

Dr. JAMES M. EAGLETON formerly of Philadelphia died at Ocala, Florida, on January 4 at the age of 70 years. He was a graduate of the Medical Department of the University of Pennsylvania and served as a surgeon in the United States Army during the Civil War.

OUR LONDON LETTER.

(From Our Special Correspondent.)

HOSPITAL FUNDS; MEETINGS—LONDON SCHOOL OF TROPICAL MEDICINE—CHLOROFORM ANESTHESIA, TWO EVENINGS' DEBATE.

LONDON, December 23, 1904.

THE hospital funds have come in for a good deal of notice during the week. The Lord Mayor held a meeting for the purpose of enlisting the help of commercial travelers. Sir J. Dimsdale moved a resolution, and told his audience that during the past year the in-patients numbered 108,687 and the out-patients, 1,771,199, at a cost of about a million and a quarter, and the only fixed income to meet this, amounted to £920,000, leaving a deficit of £310,875. Sir F. Treves, who also spoke, added statistics from the London Hospital, which would perhaps, impress the commercials, viz., that its new patients per annum averaged 183,000, requiring for treatment in the year one million pills, 3 tons of Epsom salts, 3 tons of carbolic acid, 1½ tons of chloroform and ether, 10 tons of lint, 8 tons of cotton-wool, 8 miles of catgut, and 82 miles of silk. About 40 surgical operations were performed daily in that hospital. A resolution was adopted pledging the commercial travelers to raise a fund to be added to the collection at St. Paul's Cathedral.

The Prince of Wales presided over the meeting of the King's Fund, on Monday, at Marlborough House, when Lord Rothschild, treasurer, reported that £67,999 had been received, to which the League of Mercy would add £14,000. The Executive Committee recommended the distribution this year of £8,000, of which £1,000 was provided by the Parochial Charities for Convalescent Homes. No sum is to be taken this year from the reserve.

The committee deprecate the opening of new special hospitals with small accommodation. They view with great satisfaction the removal of King's College Hospital and subscribe to the fund. On the other hand, they could not assist St. Bartholomew's in rebuilding, as that would be contributing to capital expenditure for a hospital with large endowments. They regret, therefore, that they have no power to make a grant for this purpose.

The Prince in moving the adoption of the report, expressed regret that the condition of a munificent anonymous donor had not been fulfilled, viz., the offer of securities producing over £4,600 a year, provided twice the amount were raised before the close of 1904. His Royal Highness went on to comment on efficiency and economy in the administration of the hospitals, stating that statistics had been collected from sixteen of those to which grants were made, and these figures showed some remarkable results. More than £39,000 was expended in excess of the average of these sixteen during 1903. To prevent discrepancies in expenditure, the Fund has made a comparison of the prices for the principal goods paid by different hospitals. As an example, the differences in the price of the same quality of meat equaled 3½ pence per lb. In view of this, and the obvious advantage of large contracts, the Prince suggests the possibility of the smaller institutions combining for the purpose of contracting for supplies. The Fund, as I told you at the time, has appointed a committee to inquire into the question of hospitals contributing to medical education.

Mr. Stephen Coleridge, of course, avails himself of this to push his agitation.

A decided step in advance, is about to be taken by the

London School of Tropical Medicine. Two new chairs are to be established, which will not be for teaching only, but for research in Protozoology and Helminthology. Much satisfaction is being expressed that the money for this departure will be found by the Colonial governments. You will remember that the school owes its existence to Mr. Chamberlain, when he was Minister for the Colonies, and he still retains his interest in it. He has promised to preside at the banquet next May, and meantime his successor at the Colonial office gives all the encouragement he can to the work of the school.

Chloroform anesthesia, a subject of perennial interest, has been discussed by the Royal Medical and Chirurgical Society. The debate extended over two evenings. It began with descriptions of apparatus shown and explained. The most notable of these was that devised by Mr. Vernon Harcourt, with which, by this time, you will have become familiar. Dr. A. G. Levy described an apparatus for regulating the strength of the vapor inhaled, and restricting it within the limits of safety. He adopts the plan of suction of air over chloroform, and the dilution of the vapor obtained by such a further amount of air as may be desirable. He had never exceeded 3.5 per cent., and could easily induce complete anesthesia with his instrument in 5 or 6 minutes, passing gradually from 0.5 to a 3 p. c. or 3.5 mixture, as soon as narcosis is complete. The regulator is moved to allow only 2 p. c. to continue the supply.

Dr. A. D. Waller described his "wick-vaporizer." He employs a three-wick lamp, over which a continuous stream of air is conveyed. The area of the wicks is such that at ordinary temperatures, rather more than 1 p. c. of vapor is given off to 12 liters of air per minute by one wick, while a second and third wick increases the percentage to 2 or 3.

Another apparatus was described by Dr. B. J. Collingwood. He conveys air through an inclined tube, furnished with several inlets which can be opened or closed at will. A stream of chloroform runs down the tube and according to the number of inlets open the amount of vapor taken up is controlled.

The discussion was opened by Dr. Hewitt, who said experience convinced him of the necessity of distinguishing (a) simple chloroform anesthesia from the (b) complex condition when a surgical procedure is taking place. He holds that an unembarrassed airway must be maintained during the administration. Many admirable appliances for adjusting percentages had been devised, but in use he had often seen symptoms of asphyxia occur with them. In many cases the evidence of asphyxia was so slight that only the experienced and attentive ear perceived it. With any advantages of a percentage inhaler there are also disadvantageous; they are cumbrous, complicated, and liable to get out of order and occupy the attention of the anesthetist which ought to be rivetted on the effects of the chloroform in the patient taking it. Apparatus is not suitable in some cases. All are liable to get fouled with blood or other fluids, and can hardly be sterilized. Some impose a suction effort on the patient and involve an asphyxial element. Others permit sudden penetrations from casual movement—a serious risk. All are rather slow. An experienced administrator could keep up an equable vapor of proper percentage by simple methods. With a small Skinner's frame and a drop bottle, so adjusted that it would not be easy to drench the absorbent surface, it is questionable whether there is more risk than with percentage appliances. Dr. Hewitt does not consider chloroform the best agent to begin the administration, and whenever circumstances permit, uses the nitrous oxide —ether sequence to the point when soft snoring coincides with the not yet abolished corneal reflex, when he substitutes chloroform. The chief risk of chloroform is in the excitement stage, and this plan completely eliminates it, and is, therefore, best in the ordinary run of surgical cases.

Sir L. Brunton said an inhaler might be useful in helping to maintain a steady anesthesia, but its use is limited and success depends on the care and knowledge of the administrator. It was most important to prevent shock—whether from operation, too highly concentrated a vapor, spasm and suffocation from regurgitated food and syncope from position or interference with respiration or movements of the chest or abdomen.

Dr. Dudley Buxton said a prolonged use of the Vernon-Harcourt inhaler convinced him of its value and safety as well as its enabling the anesthetist to control the degree of narcosis. In complex anesthesia a light narcosis was safer than a deep one.

Sir V. Horsley had no doubt some form of regulator would soon be generally employed. The question was one of dosage. In the induction period 2 p. c. was enough. As soon as the skin incision was made, 0.5 or even 0.4 would keep up anesthesia. A Skinner's mask might be safe for the most experienced, but for others, not for the percentage, might rise irregularly and suddenly. With the Vernon-Harcourt inhaler he had found 2 p. c. effective on animals and men. The asphyxia mentioned by Dr. Hewitt was due to overdose.

Dr. F. M. Chapman had found the Dubois apparatus excellent. It did not depend on suction. Any apparatus that did was bad.

Mr. Eve considered the Vernon-Harcourt apparatus too cumbrous, and it could not be used in some operations, as about the head and mouth. He objected to nitrous oxide on account of the cyanosis produced.

Mr. Rowell discountenanced inhalers, and said the administration could not be reduced to a mere matter of weights and percentages. He had found Dr. Levy's apparatus efficacious, but constant care would suffice; the danger was in any interference with respiration.

Dr. Scharlieb showed tracings taken in conjunction with Prof. Schäfer to illustrate the effect of chloroform given to animals with alcohol and atropine. In too large a dose chloroform excited the cardiac center unduly, stopping the heart and then the respiration. Atropine prevented this, although the blood pressure fell. Alcohol diminished the tendency to inhibit, and caused the pressure of respiration to be maintained with full percentages.

Mr. Bellamy Gardner insisted on a free airway, to secure which stertor should be relieved, whatever caused it. It was unsafe to completely abolish corneal reflex, as long as a weakly reflex continued, even in one eye, respiratory inhibition would not occur, but failure of breathing often set in as soon as both reflexes were completely abolished. If these could be abolished with the regulating appliances, they were no safer than simpler methods.

Dr. A. D. Waller said asphyxia was due to retention of the chloroform in the blood. Dosage was the most important point of all. The plenum apparatus was to be preferred to the vacuum.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

CARE OF THE INSANE—AMŒBÆ IN DRINKING WATER—CULTIVATION OF PROTOZOA—AMEBIASIS—MORTALITY AMONG PRISONERS.

MANILA, November 14, 1904.

The question of properly caring for the insane of the islands is a problem that has given the authorities considerable trouble since the advent of American rule in the Philippines. At various times arrangements have been made with the different orders of the Catholic Church for doing this work, but the number of cases that have come under observation recently has increased so rapidly that the facilities were no longer adequate. For a time the surplus was confined to Bilibid prison, but that institution is already overcrowded, and it was considered desirable to remove them from there. For a long time it was hoped that upon the completion of the sale of the Friar lands to the Government, that the La Lomboy estate, which is situated just out of Manila, could be used for this purpose. But now the property has become involved in legal complications and it is difficult to forecast when it will become available. The next most suitable place was considered to be San Lazaro Hospital, but the room at that institution was already taken up with its various departments. However, the situation demanded that something be done immediately, and accordingly the Womens' Department for venereal diseases, will be removed December 1, 1904, to a building located in Sampoloc, the district from which most of its patients are recruited. The quarters vacated at San Lazaro Hospital will be utilized for the public insane, and it is estimated that there will be room for about one hundred inmates. The new quarters will not be ideal by any means for this purpose, but they will serve temporarily, and will be better than those provided in the past.

The presence of amœbæ in the Manila and other water supplies, has recently been the subject of considerable discussion in local medical circles. One thing, at any rate, seems certain, and that is, that there still remains much work to be done with regard to the morphology and pathogenesis of amœbæ. Only a few weeks ago, the presence of amœbæ in the water supply of Mariveles was demonstrated beyond question. This water has been exclusively used by that village for three years and since its introduction diarrheal diseases have disappeared almost entirely among the natives, although before its use it is reported that diseases of this nature were quite common. But what is much more important from a scientific standpoint, is the fact that one company (over 50 men), of American soldiers, has been stationed at Mariveles for about three years, and it has been constantly under medical observation, and not one case of dysentery occurred among the soldiers which could be traced to the Mariveles water. At the quarantine station, located at Mariveles, there have been among others seven Americans under even closer medical observation

than the soldiers, and they drank this water constantly without its being boiled, sterilized, or distilled, and yet not a single case of dysentery has appeared among them. It is generally admitted among the laboratory workers of the city, that there is no way of distinguishing between pathogenic and a non-pathogenic amœbæ. The foregoing facts, however, would seem to indicate that there must be two varieties at least. Dr. W. E. Musgrave, the pathologist of the government biological laboratory, published in his recent work entitled, "Laboratory Bulletin No. 18, October, 1904. Amebas: Their cultivation and etiologic significance. By W. E. Musgrave and Moses T. Clegg. Part II. Treatment of intestinal amebiasis (amebic dysentery) by W. E. Musgrave"; is of the opinion that there is no case on record where an individual failed to show symptoms of the disease when the stools showed the presence of amœbæ for a period longer than the incubation time of dysentery. Among other things the author states that he did not succeed in growing the amœbæ in pure culture, but he was able to show that they could be better grown when the bacteria that were found in the stool with them were used for inoculating the artificial media in which the amœbæ were cultivated. By using this latter method amœbæ could be cultivated in the majority of instances (60 per cent). He was unable to grow amœbæ, unless they were in symbiotic relation with bacteria. The author also uses the word amebiasis instead of amebic dysentery, stating that the names of other affections as, filariasis, etc., are already in common use in the same way. He produced experimental dysentery in a number of monkeys and in one human being, by feeding them cultures of amœbæ. The experimental value of the dysentery produced in monkeys, however, loses much of its significance when it is remembered that it is not an uncommon thing for the monkeys kept at the government laboratory to develop dysentery without the cause being apparent. For the treatment of this disease he believes in high rectal injections of quinine solution. He does not seem to have much faith in the treatment by cold injections. He also thinks that every case in which the amœbæ are found in the stools should undergo active treatment, regardless of the fact whether there are any symptoms present or not.

That amœbæ seem to be present throughout the islands was again shown by the fact that their presence was demonstrated in a sample of water taken from the proposed site of the penal colony about to be established on the island of Paragua.

The deaths reported at Bilibid, the large Insular prison, during the nine months ended August 31, 1904, amount to a total of 207, which gives an average of 23 per month. Estimating in round numbers that the total number of inmates is about 4,000 it will be seen that the annual death rate is 69 per mille. These figures show a very large mortality. The Commissioner of Public Health has repeatedly invited attention to this high death rate and has claimed that the prison was overcrowded. Nothing was done, however, until recently when the policy was changed. Many of the prisoners were transferred to the military prison at Malahi which is situated on Laguna de Bay. It is the intention also to put others to work on road construction. Still others are to be sent to a penal colony, plans for which are now being made to establish one on the island of Paragua near the port of Puerto Princesa. It is the intention to select such of the Bilibid prisoners as have good records, to permit them to take their families with them and then to give each a piece of land to cultivate. It is believed that in a short time the prisoners would become self-supporting and that upon the expiration of their sentences they would be in better condition to become useful citizens.

USE AND ABUSE OF ATHLETICS.

To the Editor of the Medical Record:—

Sir: So many comments have been made by editors and reviewers, who are more or less in favor of athletics, regarding one statement made by me in article on "The Use and Abuse of Athletics," published in Medical Record of September 24, 1904, that I feel an explanation will not be improper.

Conclusion 5 reads: There is no evidence to prove that athletics and muscle building improve the constitution. Constitution is here considered as an inherited "general condition peculiar to an individual" (Billings' Medical Dictionary). So far as I have been able to observe there is no evidence to prove that athletes or others with built-up muscles are less liable to be attacked by any of the infectious diseases. When they are attacked the mortality rate is no lower among them than in the average individual. They succumb to diseases and severe injuries just as readily as those who are not athletes or individuals with built-up muscle. In other words, their constitutions are not improved by athletics to the extent of resisting infections or prolonging life under the conditions stated.

Brooklyn, N. Y. Robt. E. Coughlin, M.D.

Progress of Medical Science.

The Boston Medical and Surgical Journal, January 5, 1905.

Cardiac Collapse during Examination of a Post-pharyngeal Abcess.—David Cheever reports this case. The patient was a child of three years, with a history of about two weeks' duration of illness, feverishness, and anorexia. The throat was sore, and there was difficulty in swallowing. The neck was swollen, chiefly on the right side. Respiration had become labored. The child was considerably exhausted, with a pulse of 140, respiration 46, and slight cyanosis of the finger-tips and lips. Examination showed a swelling obstructing the oropharynx, but the struggles of the child made it impossible to determine its exact origin. The gravity of the situation was explained to the mother, and her consent was obtained. The necessary manipulations were carried out by force, but as gently as possible. No anesthetic was employed. The introduction of the gag caused such choking and cyanosis that it was withdrawn, with immediate relief to the symptoms of asphyxiation. The gag was again placed in position, and the condition suddenly became alarming, and breathing ceased. The child was instantly laid on the table and artificial breathing begun. The picture was that of death. With the patient in the Rose-Trendelenburg position, the abscess, which was retropharyngeal, was opened and evacuated. The amount of air which was entering the lungs was not satisfactory, so a large No. 28 French soft rubber catheter was introduced through the mouth into the trachea, and the expansion of the chest by manipulation was supplemented by direct insufflation. There was no evidence of any heart action, and cardiac massage was begun by rhythmical pressure at the rate of 60 to the minute, over the third, fourth, and fifth left costal cartilages. This massage, together with the artificial respiration, was continued for 4½ hours, till further efforts were useless. Brandy and strychnine were injected directly into the heart, the legs were bandaged firmly from toes to groin, the abdomen was manually compressed, and heaters and blankets were applied, without interruption of the respiration or massage. Death was evidently caused by cardiac collapse, due to shock. To the observers it was beyond controversy that the circulation of the blood was restored, and maintained, and that the blood was fairly well oxygenated, for feeble pulsations were detected in the radial and femoral arteries always immediately following the pressure on the heart. These pulsations were not felt when the massage was interrupted for a moment. Bleeding from incisions in the arm and neck proved the existence of circulation in the smaller vessels and capillaries, and the color of the blood and mucous membranes showed a fair degree of oxidation. The extreme exhaustion of the patient before she was brought for relief was probably a very important factor in the failure to restore the vital functions.

New York Medical Journal, December 31, 1904.

Surgical Diseases of the Sigmoid.—H. D. Niles summarizes his views in the following propositions: (1) The various pathological changes to which the physiological functions and anatomical structure and relations of the sigmoid render it especially susceptible, may be regarded as successive stages or steps of the same morbid process, rather than so many different diseases. (2) In many instances, medical treatment is fruitless and we must rely on surgery. (3) Early recognition and timely surgical intervention in initial processes may prevent later malignant disease. (4) Acute obstruction from volvulus unless promptly relieved by rectal inflation, calls for operation; so also do bowel torsions with partial or complete suture, all inflammatory or necrotic processes that include the peritoneal coat of the gut with or without angulation or stricture. (7) Inflammatory lesions and obstructive distortions of the sigmoid are by no means rare and each must be treated according to a rational surgical conception of the condition present. (8) While past surgical results are not particularly flattering, there is no reason to doubt that we shall eventually obtain just as good results as in another department of pelvic surgery. A series of illustrative cases is given.

Enuresis and Its Treatment.—J. Allman reviews the theories of etiology of this affection and summarizes treatment as (1) hygenic, (2) psychical and suggestion, and (3) physical or mechanical. He lays special stress on the massage treatment combined with atropine internally. The different steps of the massage are thus described, its object being to remedy the weakened and insufficient action of the detrusors and sphincter vesicæ: (1) the rectum is freed of feces, and massage is applied by means of the index finger to the sphincter vesicæ. The child lies in the lithotomy position and the sphincter vesicæ is gently tapped by the operator with the index finger in the rectum for half to one minute. (2) A deep circular massage is

applied over the hypogastric region for two to three minutes. (3) The patient, lying in the dorsal position with knees tightly drawn together, is told to resist while the knees are drawn apart; and, with the knees widely separated, he is asked to resist while they are drawn together. The same resistant adduction and abduction movements are also employed with the legs. .hese movements occupy about two minutes. (4) The patient, standing against a wall or door, crosses and recrosses one thigh over the other for a period of five minutes. (5) The patient is next taken across the knee, and with the side of the hand the lumbar and sacral regions are sharply tapped very frequently by the operator, thus giving a vibratory sensation.

New York Medical Journal, January 7, 1905.

The Management of Pneumonia.—O. T. Osborne insists on the ventilation of the sickroom, and the frequent moving of the patient from side to side, so as to permit hypostatic congestion of the unaffected lung. Venesection may abort the disease in plethoric patients. Antipyrine may be given in one dose of a gramme, followed by a brisk purge, with some morphine to stop the pain. Dry cupping may be used at this stage. The old treatment with aconite or veratrum, will probably have just as good an abortifacient effect. We should not overfeed. One quart of milk with two raw eggs furnishes sufficient nutriment for twenty-four hours. Expressed beef juice is a good heart muscle stimulant. Bowels should be moved once daily. High fever may be reduced by sponging with tepid water the abdomen and extremities, but not the chest. If the leucocytosis is deficient, we should give some nuclein preparation. Poultices are permissible if desired. Codeia is the best sedative for an irritable cough; for a stimulant expectorant we may give ammonium muriate with a little ipecac in syrup of citric acid. Alcohol should be used only when the circulation calls for it. One to three drams every three hours is probably enough. Nitroglycerine will equalize the circulation; strychnine restores a flagging, tensive, and irregular pulse. Adrenalin should be used cautiously at this stage if at all. Camphor and olive oil may relieve an acute heart failure. Oxygen should be used in severe cases. It keeps the patient more comfortable, though in no way curative. Chloral and ergot may quiet delirium, morphine to be used, if at all here, with the greatest caution. The ice cap may relieve headache. The value of serum treatment is as yet unproved.

Pneumococcus Arthritis.—One case is reported by W. Litterer, whose patient was a man of 36 years, with double pneumonia. He turned the critical point, and did well till the sixteenth day, when pus was discovered in the left pleural cavity, and removed in the usual way. At this time the right knee began to swell, and fluid was removed therefrom. The patient became thoroughly septic and died on the nineteenth day after his initial chill. A septic thrombosis affected the right arm for a few hours before death. Cultures taken from the knee exudate revealed in the latter the diplococcus of pneumonia; those from the pleural exudate the same organism and also staphylococcus pyogenes, the latter predominating.

The Medical News.

Disturbances of Digestion in Infants Resulting from the Use of Too High Fat Percentages.—L. Emmett Holt believes that disturbances of digestion resulting from an excess of fat are quite as serious, if not quite so obvious, as those which follow the use of too high proteids, and that they need to be studied just as carefully. Two errors are commonly made in this work: In following the book formulas, instead of using an ordinary milk, with a fat content of 4 per cent., a rich Jersey milk containing from 5 to 5.5 per cent. fat is used. Or the physician intentionally increases the fat almost without limit, for the purpose of overcoming chronic constipation. The consequences of these mistakes may be very serious. The writer has seen many of these cases, and records a few of them that he has seen within a few months. A child of 8 months, who had been overfed with fats, weighed 21 pounds. The baby had been considered a superb specimen of physical development. He was receiving in his food not less than 6 per cent. of fat. When about 8 months old, general convulsions developed, followed later by tetany, laryngismus stridulus, and fatty liver (?). The stools were found to consist of almost pure fat. It was about three months before the child recovered, and although then he was digesting well and thriving, he weighed only 19 pounds. Another baby of 8 months had been fed with high fat percentage, notwithstanding which he suffered from constipation, and moderate rickets. Acute disturbances of digestion developed, with repeated convulsions. In another case of high fat feeding, vomiting had been persistent almost from birth. The child was very much wasted, and weighed at ten months, only 2¾ pounds more than at birth. The condition of the child was alarming. Change in food and stomach-washing resulted in recovery. Not only gastric catarrh may follow the use of very high fat, but disturbances of intestinal digestion may occur, and even chronic constipation may be greatly aggravated by such feeding. The physician, in order to correctly interpret the result of milk examinations, must learn to think in percentages. Children differ very much in their capacity to digest fats, just as they do in other respects. The writer has never seen any advantage, but often much harm, from raising the fat about 4 per cent. He considers this the limit for the average child. Whenever there are marked symptoms of either gastric of intestinal indigestion, the fat should be reduced much below the normal 3 or 4 per cent.

Anal Fissure.—William M. Beach discusses in this paper the simple traumatic type of anal fissure. The mucous membrane in the anal region is very delicate, and thus easily wounded by the passage of hardened feces, the introduction of a syringe tip, or unskilful use of specula. Fissures may follow operations for removal of hemorrhoids, fistula and adenoids. Some authorities believe that painful ulcer is more frequent in women on acount of parturition. Proctitis is generally a concomitant symptom of fissure, in which is found the presence of feces that finds lodgment in one of the anal pockets. A foreign body lodged behind the crypt is apt to cause damage. In a certain number of cases, the foreign body will infect a pocket and burrow its way under the mucosa. This condition is commonly known as a blind fistula. The writer calls it a concealed ulcer. A newly made fissure is comparatively free from pain. But when the stage of sphincteralgia is reached, and the so-called "sentinel" pile is formed, severe, tearing pain follows a stool, subsiding only after a period of two or three hours, when the paroxysms of contractions cease. If the ulcer be located between the sphincters, and be irregular in shape, the nagging and sense of weight may continue the entire day. The pain is generally reflected to the sacrococcygeal region. Patients suffering from fissure are, as a rule, high-strung and melancholic. Reflex pain may be felt in the region of the bladder, prostate, urethra and testicles, ovaries, tubes and uterus. These pains may also be felt in the thighs, legs, heels, and back of the neck. Flatulent dyspepsia sometimes develops. The speculum, except in very obscure cases, is rarely required to locate an ulcer. Most diseases of the anal rectum are found between the ental and ectal sphincters. The treatment of anal fissure will depend upon the stage of the disease. In the first stage, a laxative and topical use of ichthyol will usually result in cure. When the sphincteralgic stage has been reached, surgical measures are demanded. Local anesthesia may be used. The secret is to overcome the paroxysmal contractions. Stretching the sphincter is unnecessary. The best procedure is to cut a few fibers directly back of and beneath the ulcer, and then to cut through the base of the lesion. The second incision should extend above and below the margin of the sore, and then the indurated margins should be trimmed and all the granulations curetted. Sinuses should be opened first. The margins of the wound after the operation, must be kept apart by daily insertion of the finger and the application of ichthyol or silver nitrate, gr. xx to the ounce, to a healthy granulation. The electrocautery knife, advocated by the writer, is used extensively.

American Medicine, January 7, 1905.

Tuberculosis in Japan.—S. Kitasato, after a thorough review of human and bovine tuberculosis in Japan, concludes human tuberculosis is as frequent in Japan as in the civilized countries of Europe and America. Primary intestinal tuberculosis is relatively common in adults and children, although cow's milk plays no rôle at all in the feeding of children. There are large districts in Japan, where, in spite of the existence of human tuberculosis the cattle remain absolutely free from the disease. In these regions it is not customary to consume either meat or milk from bovines. This is very important proof for the fact that under ordinary conditions human tuberculosis is not infectious for bovines, as the opportunities for infection certainly cannot be lacking. Among Japanese in general very little cow's milk is used, especially in the dietary of children. Under natural conditions the native animals show but little susceptibility for tuberculosis. If large doses of tubercle bacilli are inoculated into them either intravenously or introperitoneally, they become tuberculosis to a certain degree; they do not seem to be at all susceptible to subcutaneous infection. The imported and mixed-race animals are very susceptible to tuberculosis. Human tuberculosis is not infectious for native and mixed-race animals.

Is Mortality Necessarily Higher in Tropical than in Temperate Climates?—V. Havard asks whether mortality is much higher in tropical than in temperate climates, because of the inherent and necessary effect of meteorologic conditions, or because of violation of sanitary laws. Mortality is the resultant of many factors, of which latitude is only one, and, in the opinion of the writer, not the determining one. The chief physical elements of a tropical climate are great continued heat and a high degree of

humidity; but if the diet and habits are so modified as to diminish the calorifacient function, no injurious effect need result even from prolonged exposure to these conditions. Moist heat doubtless promotes the generation of micro-organisms, but the worst of these, those responsible for cholera, plague, yellow fever, malarial fever, and tuberculosis, make as many victims in temperate as in tropical climates under favorable conditions. The high deathrate of the tropics is due to endemo-epidemic diseases, whose cause and mode of propagation are now pretty well understood, and which, therefore, are to a large extent preventable. Yellow fever will soon be completely eradicated, malarial fever is steadily diminishing, and cholera and plague have almost disappeared from our colonies in the Pacific. Tuberculosis is more easily and successfully combated in warm countries, where patients can remain much of the time out of doors. On the other hand, most of the acute diseases which cause the bulk of the mortality in temperate and cold countries, such as pneumonia, diarrheal diseases, Bright's disease, cancer, diphtheria, scarlet fever, typhoid fever, etc., are mush less frequent and of a milder type in tropical countries. Havard concludes that climate plays but a secondary rôle in the production of disease. Mortality in any country is chiefly dependent upon its degree of civilization and the quality of its government. Thus Havana, under Spanish government, had a mortality of 36 per 1,000, which during the American occupation fell to 21.

Observations Upon Astigmatism.—Doane bases his observations upon a careful study of his last 500 cases. A cycloplegic was used in most patients of 45 and under, and in some over. Beside the usual methods for guiding the axis of astigmatism, the Maddox rod test was frequently employed. Of the 500 cases 6.2 per cent. only were without astigmatism; the right eye alone 4 per cent, the left eye alone 3 per cent.; 5.2 per cent. were hyperopic, 1 per cent. myopic, while myopia including myopic astigmatism furnished 20 per cent of all cases. Mixed astigmatism was found in both eyes in 6.6 per cent.; right eye alone 4.2 per cent., left eye alone 5 per cent.; while astigmatism "against the rule" existed in both eyes in 12.8 per cent.; right eye only 8.2 per cent., left eye only 5.8 per cent., and in both or either 26.8 per cent., which shows this disposition of the axis is not uncommon. As astigmatism is the source of various local and systemic disturbances, it requires accurate correction for allayment of symptoms. The optician is not competent to do the work, and the oculist should have the undivided support of the profession, to the end that ultimately all such patients may have the benefit of his skill.

Cerebellar Abcess.—John H. Allen reports a fatal case of —cerebellar abscess in which, owing to its indefinite course a correct diagnosis was not made. The disease began with acute otitis media accompanied by mastoiditis. Brain abscess was suspected, but it was not localized in the cerebellum. Three operations failed to reveal the seat of the disease. Post-mortem examination disclosed a large abscess of the cerebellum.

American Medicine.—E. J. Kempf treats this subject under the headings of colonial medicine and the medical history of the United States. In reviewing colonial medicine Kempf describes the difficulties which the medical men of that period had to contend with, as well as their achievements. Though there were medical colleges in America then men depended largely on the European schools of medicine. Under the second heading he sketches briefly the work done by illustrious American physicians; emphasizes the importance of American medical literature evidenced by superior journals, text-books, etc., and cites the influence of "medical societies," both national and state, which taken all together have built up a history which to-day gives the United States the foremost place in medicine in the world.

Journal of the American Medical Association, January 7, 1905.

The Passage of Different Foodstuffs from the Stomach.—W. B. Cannon believes that after food reaches the stomach all evidence suggests that the signal for an onward movement into the bowels is the appearance of free acid. This on the gastric side of the pylorus is the stimulus which opens the latter and initiates the chemical control of the sphincter. Consequently a portion of the acid chyme passes through. Duodenal acid closes the sphincter, but it is known to be the stimulus for the flow of the alkaline fluids of the pancreas. No inorganic acid is normally present beyond the first few inches of the small bowel. The acid is, therefore, here neutralized. As the neutralizing of the acid proceeds, the stimulus to the closing of the phylorus is weakened and again the stomach will open the pylorus and the process is repeated until the stomach is empty. On this theory of automatic action, the carbohydrates on which the stomach works no change go early and quickly into the intestine, where they meet their proper ferment; thus, automatically, proteids are retained in the stomach to suffer alteration by the gastric juice, and only after such alteration be permitted to go on; thus, automatically, the intestine is saved from oppression by overwhelming discharges from the gastric reservoir; and, by this same automatic mechanism, the gastric secretion, harmful to the action of the intestinal ferments, is rendered harmless because of its admission little by little into the duodenum.

The Diagnosis of Enlarged Bronchial Lymph Nodes.—Broadly stated, the physical signs of enlarged bronchial lymph nodes are, according to A. Friedländer, always those of compression, but in the early stages of the condition, it is not easy to positively determine the existence of the enlargement. An accompanying cervical adenitis is always a suspicious condition, the glands are over the sternum, being more often involved in connection with the bronchial nodes. Percussion yields no positive information. Bronchovesicular breathing on the left side with prolonged and very harsh expiration is always suggestive. Rough breathing on the right side in children must be taken cautiously. Definite bronchial compression will naturally give a diminished respiratory murmur. Other signs of importance are distended cervical veins, facial edema and atalectasis of one lung with cardiac dilatation. Recently the author has made a series of blood counts on ten patients and finds in all a lymphocytosis. This he looks upon as a reactive process due to glandular irritation. He also notes that in two diseases in which we know clinically a tracheobronchitis exists—pertussis and measles—there is a constant lymphocytosis and this he is inclined to attribute to the irritation of the tracheo-bronchial glands.

The Importance of an Early Aural Examination in Acute Diseases of Children.—A plea for such examinations is made by J. F. McKernon, who notes that aural lesions in children are common in not only the exanthemata, but also in gastro-intestinal diseases, lacunar tonsilitis, enlarged tonsils, coryza, non-pharyngeal catarrh, typhoid fever, and mastoiditis. Eczema of the external auditory canal should always lead to examination of the ear. In making the examination care should be taken that the speculum be not too large and that the auricle be drawn gently downward and backward. Cerumen calls for syringing with warm sente water previous to the use of the speculum. The various clinical conditions commonly found in the drum are described and early paracentesis advised in the event of the accumulation of inflammatory products in the middle ear.

Congenital Dislocation of the Hip.—H. M. Sherman gives his experience with arthrotomy in this condition and states his results as follows: There have been 28 hips in 20 children submitted to reduction by arthrotomy. The oldest was 11 years, the youngest was 10 months. Between these ages there were 3 in the second year of life, 3 in the third year, 5 in the fourth year, 2 in the fifth year, 1 in the sixth year, 1 in the seventh year, 1 in the eighth year, 1 in the ninth year, and 1 whose exact age is not known, but, as I remember, it must have been about 6. In each instance the femoral head has been put into the acetabulum cartilage to cartilage. Seventeen hips are known to be in stable position, with the head in the acetabulum, at times varying from 2 months to 6 years after the operation. In those children who were operated on earlier in life—below 7 years—there is ample range of motion at the hip, so that they can sit down, and can go up and down stairs, and can run and jump. In these younger children there is no tendency to ankylosis. In those who were older there has been a tendency to ankylosis, which has had to be combated, or else a practically immobile hip has resulted. This may be a permanent condition or the joint may work loose, the final result depending more on the disposition of the child—for the active child will develop motion when the passive child will not—than on any condition in the hip. Eight hips are known to be subluxated or reluxated, and the times of observation are about the same as in the group just cited. In three hips the final result is unknown. Dr. Sherman's paper is a protest against the unqualified acceptance of the claims of Lorenz. He does not believe that the latter obtained good anatomical results in half of his cases, and possible accidents of the Lorenz method are fractured bones, injured nerves, lacerated muscles, torn capsules, and ruptured blood-vessels.

The Lancet, December 24 and 31, 1904.

The Parasites of Small Pox. Vaccinia and Varicella.—W. E. de Korté claims to have discovered an amœboid protozoon in the lymph of variola, vaccinia and varicella, as well as in the analogous disease, amaas or Kaffir milk pox. The parasite of vaccinia and variola is described as an amœboid organism about 1-2500th of an inch in diameter, its protoplasm containing highly refractive greenish particles regarded by the writer as spores, which in many cases render the nucleus invisible. On the warm stage in the case

of the amoeba found in human vaccine lymph there is very active amoeboid movement, while in the case of that from small pox lymph although alteration of contour occurs no pseudopodia have been seen. In glycerinated calf lymph large amœbæ are to be observed which are regarded as encysted forms. The amœbæ can best be studied in hanging-drop preparations of the lymph itself, and since they are very easily destroyed by the manipulative process required for staining they may not be found in stained preparations, although they are capable of being stained. The writer discusses the possibility that the supposed organisms may be leucocytes and negatives it among other reasons because they persist in the lymph for as long as six months, whereas leucocytes in human blister-fluid disappear after fourteen days even though kept at the body temperature, which would hardly seem a very cogent reason in the absence of details of the origin of the blister fluid or of information of the duration of life of leucocytes in vaccine or variola lymph. No multiplication of the amœbæ by direct division and no sexual reproduction has as yet been noted.

Some Observations on Convulsions in Children and their Relation to Epilepsy.—R. O. Moon says that to many practitioners, convulsions in children are referred generally to either teething, tuberculosis, meningitis or epilepsy. He shows, however, that the matter covers a wider etiological range. Among predisposing causes are heredity and alcoholism of parents. The first fit may come from rickets, specific fevers, trauma, indigestion, emotional shock or indefinite illness. A convulsion in a child should not be looked on merely as an accidental, intercurrent event without further evil effect on the child's life and growth. The cause must be searched for and if possible removed, for if the attacks recur they may easily lead up to what really becomes epilepsy. Even where there is no hereditary factor, and assuming that a peripheral irritation is adequate in itself to produce a convulsion in a perfectly normal brain, yet the mere fact of the convulsions being often repeated makes the brain cease to be normal and creates a distinct pathological basis for the production of epilepsy. Even if this does not happen, the effect on the mental and moral condition of the child is disastrous in the extreme. Extreme unstability, liability to passionate outbursts, mischievousness and destructive tendencies are all possible dangers. Homicidal attempts have been occasionally noted. In regard to treatment, the author has found borax of great service even when potassium bromide has failed.

The Treatment of Streptococcic Puerperal Fever by Antitoxic Serum.—A. G. R. Foulerton reviews the steps of the work in this direction and then gives his own experience. In connection with Bonney, he has found streptococci of one sort or another in the uterus in 46.3 per cent. of a series of 54 cases which we have examined, and in these cases the organisms have been found under conditions which indicated that they were the primary cause of the fever. If, however, we exclude the less severe cases of fever occurring after childbirth and consider only those which either ended in death or were clinically of a distinctly serious nature we have found streptococci present as the presumable cause of disease in 62.5 per cent. These authors are convinced that there is more than one distinct species of germ concerned in these cases and describe their own method of preparing a serum. They note that with any of the sera now in use it is advisable to commence with an injection of at least twenty cubic centimeters and we must be prepared to renew this dose, if necessary, at least every twenty-four hours. They refer to the prejudice among the physicians at large with reference to untoward effects following the injections such as rashes and transient arthopathies, but do not regard them as any more common with antistreptococcic serum than with any other. A greater frequency, if present, is doubtless explained by the larger dose necessary than with other sera.

A Case of Variola Following an Unusual Course.—R Rolfe reports the case of a man of thirty years, who after exposure to the disease, presented the usual features of a moderately severe initial fever of variola, but during one night his temperature fell to normal and no rash could be found. He was vaccinated for diagnostic reasons. The temperature remained normal and he felt well. In a day or two some papules appeared, soon becoming vesicular, and it was decided that the patient had a modified variola. The case is of interest in view of the absence of all severe symptoms, and the presence of a normal temperature. The author notes that the case might have been easily overlooked or at most considered as simply influenza and dismissed without an appreciation of its gravity.

British Medical Journal December 24 and 31, 1904.

An Operation for Fixing Movable Kidney.—Andrew Fullerton describes an operation by which a movable kidney is slung up by its own capsule in excellent position, although of the angle between the last rib and the erector spinæ about 4 inches long is made from a little to the vertebral side of the angle between the last rib and the erector spinæ about a finger breadth below the rib, in order to avoid all risk of injury to the pleura. The incision is deepened down to the thin transversalis fascia which is first nicked close to the vertebral end of the incision to avoid wounding the peritoneum and intestine. The kidney is then found, and pushed up to but not out of the wound, and a small puncture is made in the true capsule, so that a probe may be insinuated and a large blister gradually separated from the posterior (vertebral) surface and outer border of the kidney. A horseshoe-shaped flap of capsule can be separated, so that the base is just above the center of the horizontal axis of the kidney. One blade of a blunt-pointed pair of scissors is now inserted under the blister, and the margin cut. The inner limb of the incision may be made a little longer than the outer, to preserve the inner tilt of the upper border of the kidney. The finger is now insinuated under the ligamentum arcuatum externum and the tissues on its deep surface peeled up, so as to get rid of the pleura should it be lower than usual. With the finger protecting the pleura, an incision is made about one-third of an inch above the lower margin of the ligament and parallel to its fibers for the whole available distance between the quadratus lumborum and the tip of the last rib. The last dorsal nerve should be avoided. A pair of Kocher's artery forceps is pushed through the slit that has been made, and the free end of the separated capsule is drawn through, spread out, and stitched down to the ligament and neighboring parts with formalin catgut or silk. The kidney is thus slung as on a pulley. If necessary, stitches may be used to unite the capsule at the margins of the raw surface to the lumbar fascia at the sides and below. The wound is sutured in layers. The operation is easy to perform and according to the writer's short experience, fixes the kidney effectually.

A Note on the Treatment of Thrombosis of the Superficial Veins of the Lower Extremities.—C. Mansell Moullin says that prolonged venous stasis with consequent malnutrition of the walls of the veins is the usual predisposing cause of superficial thrombosis, and some trivial injury, perhaps scarcely noticed at the time, does the rest. The usual treatment for these cases is prolonged rest in bed with the leg elevated, and covered either with lead lotion or with some mixture of extract of belladonna and glycerine. The writer has, however, for some years abandoned this treatment and has at the earliest opportunity excised the whole thrombosed part of the vein. His results have been excellent. The wound is sound in a week and the patient can get up without any risk of embolism, deep thrombosis, or recurrence. In one case, both internal saphena veins were plugged right up to the saphenous opening. The vein was carefully exposed, and slit open close to its termination, the clot was withdrawn and a catgut ligature was tied around the vein immediately below its junction. The rest of the vein was then excised, and the patient left the hospital within a fortnight. Deep communicating branches, the anatomical situation of which is fairly constant, should, if thrombosed, be treated in the same way. A moderate degree of inflammation does not seem to make any difference. It subsides as soon as the vein is removed. In such a case the wound should not be sewn up tightly, as there is sure to be a considerable amount of oozing afterward.

Chrysoidin in Trypanosomiasis.—Andrew Balfour found some years ago that chrysoidin was extremely lethal to fish. This was true when even very dilute solutions were used. This of all the dyes that were used in various experiments seemed to have the greatest penetrating power. It appeared to pass readily into the blood stream and undoubtedly possessed a marked affinity for the central nervous system, staining the brain and spinal cord a brilliant yellow. Although so toxic to fish and other low forms of life, comparatively large doses could be given with impunity to rabbits. Its toxic action, the writer believes to be due to the fact that it is an azo compound. Although its effects are very similar to those of methylene blue, it is more poisonous and more speedy in action. Chrysoidin has met with favorable results when given in bilharzia disease. The writer thinks that it may be found beneficial in cases harboring protozoal blood parasites, and hopes to induce those who have the opportunity of trying it in cases of trypanosomiasis to do so.

A Tubal Pregnancy of Some Years' (?) Duration.—F. Hurry Fenwick was called to see a patient of 45 years, who had a large abdominal tumor, fecal urine, pneumaturia, hectic temperature of long duration, and great emaciation and cachexia. Cystoscopy showed that the bladder was comparatively healthy. It bulged forward, and under the prominence was a fistulous opening. The diagnosis of suppurating ovarian dermoid was made. An incision was made into the tumor above the pubes. Pus, feces and gas escaped in large quantities. After thorough irrigation, a bare fetal femur appeared and then a humerus. A macerated fetus was now felt lying in a puddle of corruption.

The writer tried to open the peritoneal cavity at the sides in order to dissect out the wall of the fetal sac, but the bowels were adherent to it and were also softened. The cavity of the sac had to be packed. The patient rallied, but died in a few hours. The patient gave the history of having become pregnant 8 years before. The various symptoms of pregnancy had gradually disappeared, but a large "lump" remained in her side. Three months ago she received a hard blow on this lump. Two days later she suffered great pain in her abdomen and she had been sick ever since. Post-mortem examination showed a left tubal pregnancy which had suppurated, becoming adherent in every direction and had finally perforated into the bladder and sigmoid bowel. The fetal sac could not be dissected away from the hollow viscera which surrounded it. The bones showed the fetus to be about the fifth month.

A Preliminary Note on the Bacteriological Findings in Seven Cases of Enlarged Prostate.—L. S. Dudgeon and Cuthbert Wallace in their examinations of enlarged prostates have discovered that in the greater number of cases the tumors removed from the prostates showed unmistakable signs of infection by microorganisms, and that in some instances the infecting organisms were the same as those found in the urine. These observations, to a certain extent, lend support to the view that the initial lesion in prostatic enlargement may in certain cases be a septic infection from the bladder. Yet it is difficult to accept the view that all such enlargements are due to such a cause as this would mean septic infection of a large proportion of bladders in individuals over 50 years of age. The most careful antiseptic precautions were observed in all of these proceedings. Although a medium of blood agar was used in each case for the examination of the prostatic tumors, gonococci were not isolated. Pure cultures of the staphylococcus albus were obtained; the bacillus coli was also isolated. A brief history of several cases is given.

A Test for Constipation.—C. Graham Grant believes that many people complain of constipation when this condition is not really present, and also that many individuals think that their bowels are in good working order when constipation really exists. He believes that the test depends upon the time consumed by the passage of food. If the morning motion consists of the débris of the food consumed during the previous day, constipation does not exist. If, instead, the débris of food consumed some days previously forms the stools, constipation does exist. In many cases this is an important matter to determine. The writer suggests giving a tablesponful of animal charcoal to doubtful subjects and time its appearance in the stools. In normal persons it comes through in 24 hours. In one case it delayed for a week. This patient, moreover, thought because she went to stool every morning that she could not be constipated. This test is of value in suspected intestinal obstruction. It is also possible by this test to convince mothers that their children do not need castor oil every night. The gritty charcoal is unmistakable in the excreta.

Berliner Klinische Wochenschrift, December 12 and 19, 1904.

The Physical Properties of Solutions in the Human Stomach.—Sommerfield and Roeder were able to make freezing point determinations on human gastric contents uncontaminated with saliva, by using as a subject a girl of ten years old who in consequence of total cicatricial occlusion of the esophagus was fed through a gastrostomy wound. It was found that all solutions introduced into this stomach suffered a change in their molecular concentration, those istonic with the blood and those hypertonic becoming more dilute, while those hypotonic to the blood increased in density. Hypertonic solutions even after a sojourn of several hours in the stomach, reach a point which is still above the freezing point of the blood and therefore leave the stomach in a hypertonic state. In no case could any augmentation of the amount of fluid in the stomach be detected.

The Eye Lesions of Chronic Lead Poisoning.—L. Lewin gives a list of occupations in which more or less serious damage to the eyes of the workmen is likely to result. Substances likely to be dangerous to workers are carbon disulphide in the vulcanization of rubber, ethyl bromide, mercury in all forms, wood alcohol, arsenic, dinitro-benzol, anilin and anilin colors, carbonic oxide, hydrogen sulphide, lime, chinon compounds and lead. The last of these is often underestimated in importance but forms a most treacherous and dangerous foe to the workman. The author cites thirty different trades in which the use of lead was followed by damage of greater or less degree to the eyes of 130 patients. The gravity of the condition is shown by the statistics of 114 cases in which cure could be effected in only 40, while atrophy of the optic nerve was noted 36 times. The ocular symptoms caused may be of many sorts and degrees of intensity but even when cured always leave the patient with a susceptibility to the poison which makes a continued exposure very hazardous.

Hypochondriasis.—Schott maintains that hypochondriasis is not a nosological entity but that it represents one of the manifestations of degeneration. Hypochondriac states are often associated with neurasthenia and hysteria, and may appear in any form of insanity. In dementia praecox hypochondriasis demands especially careful analysis owing to the danger of confounding it with simple neurasthenia or hysteria. In aggravated cases the tendency to suicide or self-mutilation must always be reckoned with and in hypochondriac insanity there is always more or less danger to the attendants. A state of hypochondriasis always demands a careful physical examination and all sources of peripheral irritation must be removed as completely as possible. The treatment must be directed to the underlying condition, but the use of drugs should be restricted.

Syphilitic Infection of Horses.—Piorkowski reports interesting results following an attempt to infect a horse with syphilis. The successful infections recently made by various observers on monkeys led the author to make use of the blood of patients who had been subjected to a more or less vigorous mercurial treatment, thinking that in this way a certain reactive effort on the part of the parasites would give rise to the formation of an especially active serum. Small amounts of blood were taken from 80 patients in various stages of the disease and injected into a horse, either subcutaneously or intravenously, in quantities of 5-10cc. Each injection was followed by a moderate febrile reaction and the injections were repeated as soon as this had subsided. The treatment was well borne, and four weeks after the first inoculation a fairly well marked papular cutaneous eruption appeared, which both in its gross characters and microscopical structure was pronounced syphilitic in nature by various specialists. Glandular enlargements also developed. The serum obtained from the horse was found to be harmless to small animals and the author is prosecuting further control experiments on other horses.

Münchener medizinische Wochenschrift, December 13 and 20, 1904.

What Is the Value of Leucocytosis in Appendicitis?—Federmann takes issue with the writers who have recently decried the value of leucocyte counts in appendicitis and says that the degree of leucocytosis before operation furnishes the most reliable prognostic evidence we have. Operation performed when leucocytosis is high gives a good prognosis, but the outlook is unfavorable if the clinical symptoms are severe and leucocytosis is slight or absent. The value of the information obtained from the leucocyte count depends entirely on the manner of its interpretation, for all the other symptoms and the stage of the illness must also be taken into consideration. In all cases of severe infection the leucocytosis is high, 20,000 or over, in the first few days, but this does not necessarily indicate the presence of pus. If the patient's powers of resistance become impaired the leucocytosis drops while the other symptoms increase in gravity. Simple appendicitis without involvement of the peritoneum only rarely exhibits a leucocytosis of 20,000, and if present this rapidly subsides to normal together with the other symptoms. A leucocytosis of 20,000 in the first few days is an indication for prompt operation, as well as a low count with grave clinical signs. Moderate counts, between 12,000 to 20,000, in general are to be subordinated to the other features in coming to a conclusion as to the line of treatment.

The Treatment of Bony Ankylosis of the Elbow.—Schanz describes a plan of operation which he employed with success in a case of ankylosis of the elbow following rheumatism. On exposing the joint it was found that the ulna and humerus were the seat of a complete bony union which did not, however, involve the radiohumeral articulation. The plan of procedure consisted in chiseling out enough of both bones at their point of union to leave a crevice 1 cm. wide. A pedicled flap of subcutaneous fatty tissue was dissected up and pushed into the space between the ends of the bones and the wound sutured. The result of the operation was a painless restoration of usefulness to the arm without any evidence of a tendency to relapse, and the author warmly recommends a trial of the interposition of fat flaps in all similar conditions.

A Case of Chromhydrosis.—Platter describes the case of a woman of middle age who suffered severely from attacks of migraine. These could be controlled only by the use of large amounts of coal tar analgesics, which had been consumed in great quantities for about three years. For the same length of time the patient had suffered from a very profuse avilary secretion of deep blown, thick sweat, which required daily changes of linen. Under vigorous hydropathic treatment the migraine was relieved to such a degree that the analgesics could be dispensed with and the chromhydrosis disappeared also. A single dose of the coal tar preparation sufficed to cause a return of the condition for twenty-four hours.

Modern Theories of Eclampsia.—Wormser and Labhardt have conducted further experiments in an attempt to establish the value of certain modern views as to the nature of eclampsia. The three most important of these theories are those of Veit, Ascoli, and Weichardt. The first author assumes that syncytial elements washed into the maternal blood stream are the cause of eclampsia. Ascoli accuses an overproduction of syncytiolysius, and Weichardt believes that in the process of syncytiolysis, syncytiotoxins are produced and give rise to the disease. The author's experiments were conducted on the serum of rabbits adapted to placental extract obtained from fresh placentæ washed free from blood and hashed under the most scrupulous aseptic precautions, but, like those of other investigators, the results obtained showed so many inconsistencies compared with preceding observations that the authors feel the subject is still in too unsettled a state to permit the formation of definite conclusions. Although the matter rests in so unsatisfactory a position the authors do not go so far as Pollak, who, in consequence of the negative nature of his similar experiments, discredits the possibility of applying the modern lore of immunity to the question of eclampsia and seeks for the cause of the condition in maternal intoxication with products of fetal metabolism. A case of Hitschmann's in which eclampsia accompanied a mole pregnancy without a fetus proves that this theory alone is not sufficient to explain the phenomena, and certainly does lend some color to Veit's hypothesis.

Leucocyte Counts and Early Operation in Appendicitis.—Berndt, who is a warm advocate of early operation in this condition, says the leucocyte count, while of value when high, may be misleading, as suppuration may be present with a normal number of white cells. A more reliable index as to the nature of the case is to be found in the pulse. The behavior of the pulse is the decisive factor in determining between the severe and mild types of appendicitis and its abnormalities are earlier and more regular in their appearance than any other symptom. If a pulse rate of over 100 accompanies the initial symptoms of pain, vomiting or nausea, the case is to be regarded as a serious one and should be kept under constant observation, the pulse being recorded hourly. If the rate remains at the same height or rises during the ensuing six to twelve hours, operation is indicated and delay is dangerous. Early operation performed by a competent surgeon is without danger, and cases seen some time after the onset of the symptoms should be promptly operated, no matter what the day of the disease, if the pulse rate exceeds 100. Early operation offers the only means of reducing the mortality from appendicitis.

Deutsche medizinische Wochenschrift, December 22, 1904.

A New Method of Obtaining Antibodies.—Loeffler says that considerable difficulty has been experienced in obtaining antibodies from animals, owing to the fact that the substances injected were often infectious and killed the animals. By experiments on various forms of albumen, bacteria and albuminous substances, such as portions of organs from cases of various diseases, carcinoma, serpent venom, etc., he has established the fact that it is possible to sterilize these agents without impairing their antibody producing power. The substances are first dried at low temperatures and placed in a desiccator till there is no further loss of weight. They are then subjected to a temperature of 150° C. in a closed drying oven for a period of half an hour. Both agglutinins and bacteriolysins can be produced by this method, as the preliminary heating appears not to introduce any disturbing factors. The plan offers the further advantage of permitting the preservation for indefinite periods of material for such investigations.

The Effect of Sea Water on Sunlight.—Leo has investigated the interrelationship existing between sea water and the sun's rays. The fact that there must be some intensifying influence present at the seashore is shown by the greater severity of the solar erythema caused by exposure under these conditions, and the author's experiments bear out this inference. Oxidations in certain chemical bodies were produced when these were dissolved in sea water and exposed to sunlight, but did not occur in the dark or when plain water was employed. The decomposing effect of light on enzymes and yeast cells is not increased by the presence of sea water, and in some instances it appears to reduce the photodynamic activity of the light. Boiled sea water, as well as that artificially prepared, seems to have the same photochemical properties as the natural product.

The Protective Action of the Zinc Chloride Eschar.—Bröse, who is an advocate of zinc chloride as a cauterizing agent, has studied its action on wounds as a protective against infection. Experiments were made on rabbits and on bacteria directly. The author concludes that even in concentrated solutions, zinc chloride is wholly devoid of antiseptic properties, but that the eschar it produces when brought into contact with aseptic wound surfaces absolutely prevents subsequent infection with pathogenic organisms. The penetrating powers of the caustic are so great as to give it the ability to protect the wound against infection even if it is not applied until the expiration of a minute after the infective agent. The eschar produced is not a culture medium, for bacteria and pathogenic organisms cannot be recovered from experimental eschars two or three days after their application to it.

French and Italian Journals.

Treatment of Frontal Sinusitis.—Sebileau declares that a certain number of cases of acute frontal sinusitis recover after very simple operative procedures. It is even probable that a certain number have recovered without operation. When the affection is chronic, intervention is indicated—destruction of the fungoid growths. After resection of the anterior wall of the sinus, the writer cleanses the cavity, and removes all of the diseased parts, avoiding injury to the cribriform plate. It is to the destruction of this bone that the greater number of cases of meningitis are due. The writer is careful not to cause any pressure by means of the dressings. In one patient, he replaced the wall by a gold plate. The result was satisfactory.—*Journal des Praticiens,* December 3, 1904.

Apropos of the Mechanism of Propagation of Cancer of the Breast.—According to Tuffier, the propagation of cancer of the breast can occur in two ways, which are well known. One of them, however, has not been described. It concerns those small cancerous foci that are seen to reappear at a certain distance from the cicatrix. These foci develop in the thickness of the skin and are completely independent of the lymphatic system. Tuffier has been able to isolate and examine one of these neoplastic nodules, and has determined that the epidermis was intact and that the glandular cancerous cells were in the hair follicle. The patient had had an ulcerated cancer of the breast, and it was probably by means of the dressing which she applied to the tumor that the propagation to the hair follicle took place.—*Le Bulletin Médical,* December 3, 1904.

Serious Lesions from the Bite of a Viper Treated by Calmette's Serum.—Moindrot cites a case in point, the patient being a child of 8 years. While playing near a woodpile, the boy was bitten by a viper, on the right ring-finger. The wound was not considered serious, the child's parents being satisfied with pressing the injured finger, thus forcing out a small quantity of blood. A few minutes later the boy began to complain of a sensation of distention in the region of the injury, a sensation due to edema, which increased at an alarming rate. On his entrance to the hospital, seven hours later, the patient's condition was very grave. There had developed edema of the fingers, hand, entire right arm; of the cervical region of the same side, and of the anterior surface of the thorax as far as the lower border of the floating ribs. This edema was slightly painful and rather tense. These parts were cold and livid, and spotted with ecchymotic areas. The wound itself had no special features. The general condition was bad. The child could not stand up; he was indifferent to all about him, and groaned when he was examined. The pulse was weak, compressible and irregular. The extremities were cold. The respiration was accelerated—30 per minute. No urine had been voided since the accident. Although the condition seemed desperate, Moindrot made an injection of 20 cubic cm. of Calmette's serum, at the same time making a crucial incision at the site of the wound, bathing it in a solution of permanganate. This treatment was followed by the application of a wet dressing to the entire arm. The child was put to bed, and artificial heat applied. Caffeine was injected as well as artificial serum. From the next day, the condition was more satisfactory. A series of injections of permanganate was given in the lower thoracic and in the cervical regions. Recovery took place by degrees, although it had been seven hours after the accident before treatment was instituted.—*Revue Française de Médecine et de Chirurgie,* November 28, 1904.

The Nervous Ganglia of the Stomach in Some Gastric Diseases.—D'Amato refers to experiments made by him with reference to the alteration of the nerve ganglia in gastric diseases. Gastritis produced in dogs by administration of alcoholic mixtures causes changes in the plexuses of Meissner and Auerbach, consisting of hyperemia, chromatolysis, vacuolization, cariolysis, and atrophy of nerve cells. In cases of long continuance there was increase in the formation of connective tissue, even amounting to glandular sclerosis. They observed cases of pyloric cancer and chronic gastritis in man, and found the same lesions there. The glandular lesions may be explained as the result of poisonous substances, either introduced into or formed in the stomach. Such lesions, together with the alterations in the mucous membrane, are the basis of gastritis. What symptoms they produce we cannot as yet say.—*Rivista Critica di Clinica Medica,* November 19, 1904.

Weather Influences. An Empirical Study of the Mental and Physiological Effects of Definite Meteorological Conditions. By Edwin Grant Dexter, Ph.D., Professor of Education at the University of Illinois. With Introduction by Cleveland Abbe, LL.D. New York: The Macmillan Company; London: Macmillan & Co., Ltd. 1904.

The effects of weather changes upon physical and mental states are so evident that literature and folk-lore are full of references to them. The popular beliefs are contradictory, as nothing exact was ever known of the matter, and we have been content to state that we are "under the weather" as sufficient explanation of every abnormal act, ill feeling, or minor ailment. Professor Dexter has, therefore, performed a valuable work in classifying an enormous number of abnormal acts, as to their commission in different states of the weather, and has discovered unsuspected relationships, the results in some cases being the opposite of popular beliefs. His investigations were primarily undertaken to discover the reasons for those occasional periods of bad work or bad conduct of school children, which have been the despair of teachers. He has shown, for instance, that the deportment of children is best in the winter months, but that it begins to deteriorate in the spring, and continually deteriorates to a maximum of badness in June; it is good on very cold and very hot days, but is at its worst in moderate temperatures; it is best on days of high barometer, and when the humidity is greatest—the latter being contrary to general belief.

It is evident that if the reasons for these proved facts can be found, educators will be able to avoid conditions which are undoubtedly injuring school children. Unfortunately, Professor Dexter's explanations of the phenomena cannot be wholly accepted, as he has not touched upon the effects of light and darkness—a matter which is of great medical importance, since we have learned that concentrated light rays have a profound influence upon living protoplasm, and that blondes are more susceptible than brunettes. Nor has he discriminated between different physical types, for the weather conditions which may be the most comforting to the negro may be so irritating to a Caucasian as to be the determining cause of an illness or some abnormal act. He finds that abnormal acts are greatly lessened on dark, cloudy, and rainy days.

The recorded data in the book also prove that certain meteorological conditions do vary the number of cases of suicide, drunkenness, sickness, and arrests for insanity and crimes, and that the variations are in definite directions. Though the generalizations are of purely scientific value now, they are sure to lead to practical therapeutic and preventive measures when the causes of these results are worked out. Manufacturers, who find that certain kinds of weather reduce the output of the factories, may counteract the evil by more sanitary buildings.

On the whole, the work is of value, and the hope can be expressed that there will be more of like kind. Americans are all far from their normal European habitat, and are anxious to know if they are really being injured by the changed conditions, and why.

Appendicitis and Other Diseases About the Appendix. By Bayard Holmes, B.S., M.D. Professor of Surgery in the University of Illinois, Professor of Clinical Surgery in the American Medical Missionary College, Chicago; Attending Surgeon the Chicago Baptist Hospital. New York: D. Appleton & Company, 1904.

In the first section of this work the author deals with the subject of appendicitis exhaustively. From the initial catharrhal process to the cystic, ulcerative, or gangrenous stage the appendix is laid bare in all its iniquitous doings. The symptoms produced by these pathological changes and eventualities, with the essentials of differential diagnosis are herein presented with telling directness. In this connection the work is to be commended for the frequency with which actual cases are cited with the operative findings illustrative of the particular phase of the disease under consideration. These pen portraits constitute a valuable library of silent witnesses to the reader who is seeking clinical pictures that will explain some confronting symptomatic problem. Apropos of this, the chapter on "Obscure Forms of Appendicitis" is a plea for persistent investigation along the lines of modern diagnostic methods, until the appendix is acquitted or convicted of being responsible for existing conditions.

In regard to treatment, the author condemns in no soft language the fatuous complacency with which some authorities recommend palliative treatment for the "cure" of the diseased appendix. First and last, he adheres unswervingly to his contention that "every case of appendicitis is a surgical condition, *i.e.* for appendectomy. . . . . In acute cases operate at once, in chronic, as soon as suitable surroundings can be secured. . . . . There is no condition from the time that the disease is relatively and exclusively diagnosed to the last expiring breath of the patient in which immediate operation is not indicated."

Intussusception, perforating typhoid ulcer, and carcinoma of the intestinal tract, are considered briefly but to the point, in the second section. The author focalizes his diagnostic limelight on only the crucial symptoms of the above conditions, and familiarizes the reader with the indications for laparotomy in each respective instance. Few practitioners, we venture to say, can read this work without having their diagnostic range amplified, and the courage of their convictions in regard to the surgical aspects of appendicitis augmented.

Mental Defectives: Their History, Treatment and Training. By Martin W. Barr, M.D., Chief Physician Pennsylvania Training School for Feeble-Minded Children, Elwyn, Pa. Philadelphia: P. Blakiston's Son & Company, 1904.

Dr. Barr's experience of nearly twenty years in the care of the feeble-minded affords ample justification for an authoritative expression by him upon a subject of the profoundest practical importance and having to do with matters involving true philosophic insight of the highest order. Although the volume before us is addressed more especially to laymen—parents and teachers—medical men and others will find in it much of the greatest interest related in a most attractive manner. The work deals especially with idiocy and imbecility in their various gradations, and also mere backwardness or mental enfeeblement. An interesting chapter is devoted to the history of the subject given at some length. This is followed by a discussion of classification and by a chapter on etiology and one on diagnosis, prognosis, and death periods. Training and treatment are considered with especial fullness in a most admirable manner. Craniectomy as a therapeutic procedure receives unqualified condemnation, while asexualization is as heartily endorsed as a means of preventing the propagation of defectives. Cretinism and myxedema, microcephalus and hydrocephalus, epilepsy, idiots, savants and insanity, echolalia, and adenoma sebaceum are discussed in separate chapters. Sixty-five pages are given up to reports of illustrative cases and a separate chapter to a full consideration of the case of Samuel Henderson, a juvenile murderer, and a discussion as to his responsibility. The final chapter contains a number of stories relative to mentally deficient children, while a full bibliography and an ample index complete the volume. There is no chapter on pathology and morbid anatomy. The volume is warmly to be commended to all interested in the subject of mental deficiency, physician and layman alike.

A Treatise on Bright's Disease and Diabetes, with Especial Reference to Pathology and Therapeutics. By James Tyson, M.D., Professor of Medicine in the University of Pennsylvania, etc. Second edition, illustrated. Including a Section on the Ocular Changes in Bright's Disease and in Diabetes. By George E. de Schweinitz, M.D. Professor of Ophthalmology in the University of Pennsylvania, etc. Philadelphia: P. Blakiston's Son & Company, 1904.

Since the appearance of the first volume of this treatise twenty-three years ago our views on the nature of nephritis and diabetes have been modified in many more or less important particulars. Theoretical investigations have been accomplishing much in these as in all other branches of medicine, but the practitioner still finds that clinical experience is the basis of success at the bedside. The author's advantages in this respect have given him the right to speak as one having authority, and the volume, therefore, contains much of the greatest interest and value in everyday practice. The classification of the different forms of nephritis adopted represents the present standpoint of most authorities and the descriptions of the pathological anatomy of each condition are clear and detailed. The author's methods of treatment are fully described and will prove most suggestive to all clinicians. Dr. de Schweinitz has contributed to this edition chapters on the ocular changes in Bright's disease and diabetes which should stimulate practitioners to make more frequent use of their ophthalmoscopes. The illustrations throughout are well chosen to elucidate the text and the numerous colored plates, including three excellent depictions of changes in the fundus oculi, are of admirable execution. The only criticism that might be made is that the chemistry of the urine is somewhat inadequately treated. Of course, the book is not intended as a handbook of laboratory methods, but having decided to devote as much space as he does to the examination of the urine, the author might well have gone a little further and have greatly increased the practical utility of the volume by adding to the scanty number of tests described some others of the methods now in everyday use, as, for example, Spiegler's tests for albumin and the phenylhydrazin test for sugar.

Society Reports.

WESTERN SURGICAL AND GYNECOLOGICAL ASSOCIATION.

Fourteenth Annual Meeting, Held in Milwaukee, Wisconsin, December 28 and 29, 1904.

(Continued from page 35.)

Surgical Diseases of the Pancreas.—Dr. D. C. Brockman of Ottumwa, Iowa, stated that recent studies of the pancreas showed the importance of internal secretion from the islands of Langerhans; also the influence of regurgitation of bile into the pancreatic ducts, as a cause of pancreatic inflammation. Biliary disturbance was mentioned as the chief cause of pancreatic disease, and the author stated that pancreatic cysts were believed to be mostly due to this cause. He reported three instructive cases of cyst of the pancreas, and then gave an outline of inflammatory troubles, with special reference to the diagnosis and treatment of acute and chronic pancreatitis.

Cysts of the Pancreas.—Dr. D. W. Bashaw of Wichita, Kansas, followed with a paper on this subject. He referred briefly to the physiological anatomy of the gland, in order to elucidate the principles underlying the formation of a cyst of this organ. He recounted the symptomatology, and pointed out the difficulty attending the diagnosis. As to treatment, Gussenbauer was the first to marsupialize the sac, and since then this had been a favorite procedure with most surgeons. The only question regarding this method was whether to attach the sac to the abdomen, and incise at once, or to operate *à deux temps*. If there was plenty of time, and the cyst was not so large that a day or two might make any difference in the result, he thought it was better to operate in two stages, stitching the sac to the peritoneum and muscles, and opening two or three days later. Excision of the sac was not often practical, but might sometimes be attempted. Often such a course would expose the patient to the risk of contaminating the peritoneal cavity with pancreatic secretions. He reported the case of a tumor of the pancreas in a woman 62 years of age. The tumor was removed. The patient left the hospital at the end of seven weeks, and he had not seen her since. The woman's dyspeptic manifestations were better after the operation than before, but were not entirely relieved. About the first of December, the patient began to have serious trouble with her stomach, and called a physician, who was able to outline a tumor in the region of the pylorus, which he diagnosed as cancer of the stomach.

Dr. William D. Haggard thought inflammations of the pancreas occupied the most prominent position in the future development of surgery. Disease of this organ was closely allied to the surgery of lesions in the upper abdomen. When one stopped to think how our knowledge had been amplified in the last two years relative to this sequestered organ, and when one considered that many cases of so-called gastritis, intestinal obstruction, etc., were after all, probably instances of pancreatitis, it made surgeons realize that the lesson had been appreciated; we had not yet mastered the diagnosis of this as well as other lesions, but nevertheless more attention should be addressed to lesions of the pancreas than had been done in the past. He referred to the three types of infection, and called attention to the excellent work done by Opie, Robson, and others.

Dr. Brockman, in closing, expressed the opinion that pancreatic cysts were not so uncommon as had been supposed. He had had four such cases in the last twelve or fourteen years.

Excision of the Elbow Joint for Traumatic and Arthritic Ankylosis.—Dr. B. Merrill Ricketts of Cincinnati, Ohio, read a paper on this subject, in which he drew the following conclusions: "(1) Excision of the elbow joint for ankylosis, due to any cause, at any age, is a most rational procedure. (2) If possible, it should be done before or at the time ankylosis is complete. (3) A posterior median incision is the most practical. (4) With care the operation can be done without injury to blood vessels or nerves. (5) Drainage should always be provided for. (6) The arm should be placed upon a right angle splint. (7) Results are better when only the articulating surfaces are removed. (8) If there is complete bony union of the articulating surfaces, much more bony tissue must be sacrificed, because disarticulation cannot be accomplished. (9) All soft structures cut transversely will unite, but new insertions are formed which destroy their function. (10) All attachments of tendons and muscles should be preserved. (11) All periosteum should be preserved. (12) If excision of the joint is complete, leaving only the ends of the shafts, flail joint can be prevented by approximating their ends with kangaroo tendon at the time of primary operation. (13) Wire or nails may be used, but their removal sooner or later will be imperative. (14) Flail joint rarely results from any form of excision, but is more likely to be found following excision of the entire joint. (15) If flail joint results, a mechanical device may be employed. (16) Injections of alcohol or one or more of the various astringents will increase fibrous tissue both in quantity and density."

The Operative Treatment of Fractures and Sprains.—Dr. A. E. Benjamin of Minneapolis, Minn., stated that frequently fractures were not recognized, and that complicated joint fractures without operative tretament gave poor results. All fractures should be examined with the *x*-ray to diagnose positively and locate the injury. The ordinary form of treatment of even simple fractures often resulted in a deformed and crippled limb. The term ununited fracture was a myth; the condition was invariably due to some preventable cause. The habit of using the *x*-ray in all fractures led to more operative measures, although without its use diagnosis was frequently impossible and treatment uncertain. There was frequently as great a subcutaneous injury in a simple fracture as in a compound fracture, and it was just as essential that an operation should be performed in such cases, in order to prevent a lasting injury to the nerve and muscle tissue. By an operation upon these fractures drainage was established, pain and fever lessened, exostosis and the organization of the exudate were less permanent, and necessarily there followed less permanent injury to the soft structures. Associated with fractures there was frequently a sprain or a tearing away of ligaments and cartilages, and dislocation. The progress of a joint that had been sprained was often slow and discouraging, resulting in a weak and insecure union of ligaments. It was advisable to operate upon a number of sprains, especially where there was a great deal of exudate and pain. By the operative method drainage was established, pain relieved, the ligaments could be stitched in their natural place of habitation, the convalescent period was shortened, and a greater proportion of cures resulted.

The Surgical Considerations of Gastric Dilatation.—Dr. A. M. Pond of Webster City, Iowa, after considering the etiology of gastric dilatation, stated that in the last three cases of gastric dilatation due to impairment of the stomach wall he had modified the standard operation. Sufficient time, however, had not elapsed to warrant a description of the operation. The last case was operated upon in June. In each instance a very satisfactory result was obtained The success of the operation depended upon two very important factors, patency of the pyloric orifice, and the ability of the gastric muscle to regain its normal tone. The author believed that gastric dilatation was usually a sequence rather than a primary cause of discomfort, and that it owed its presence to some disturbance of the elemental dynamics of digestion. It was, on close analysis, merely one of a symptom-complex of the upper abdomen, but a very valuable one, the importance of which should be included in the consideration for operative restoration.

Treatment of Acute Perforations of the Upper Abdominal Viscera.—Dr. Van Buren Knott of Sioux City, Iowa, pointed out the importance of the early recognition of

such an accident, saying that an accurate diagnosis as to which organ was involved was neither possible nor necessary at all times. The symptoms of gastric or duodenal perforation would usually be more intense than those of perforation of the gall-bladder. Previous history of the case was of importance in making a differential diagnosis. The treatment was successful in direct ratio to the promptness with which it was instituted. The resulting peritonitis was the most important result of the accident, and its treatment in the various cases was similar. He emphasized the value of posture in treatment.

Pneumatocele.—Dr. L. L. McArthur of Chicago reported a rare case of pneumatocele, saying that it was a gas-containing tumor of the cranium, very rare, there being but thirty-two recorded cases since 1741. It always originated in connection with either the mastoid or frontal sinuses. It was not to be confused with emphysema, which was gas in the cellular tissue. Pneumatocele was gas beneath the pericranium. Incident to the elevation of the periosteum, were secondary bony outgrowths, giving the tumor a peculiar feel. In the preantiseptic era the simple benign pneumatocele became a dangerous affair, because of the frequent connection with mastoid sinuses, with the potential septic meningitis. Since antiseptic surgery had become well established, all of these cases ended favorably.

The Value of Skiagraphy in the Treatment of Fractures.—Dr. H. A. Sifton of Milwaukee, Wis., exhibited in connection with a paper on this subject numerous skiagraphs. He was of the opinion that, when it was possible, the Roentgen ray should be used in the treatment of every fracture. It had its deceptions, but these meant nothing to the physician who had made a study of the subject and was familiar with the conditions under which the skiagraph was taken. Some urged its use in the obscure or complicated cases only, but the difficulty with this plan was that we could never tell whether or not a fracture was complicated until a radiograph of it was taken. It was the surgeon's duty to do his best for the patient, and to do this he should look upon every case of fracture as complicated, until it had been shown to be otherwise by a good radiograph. A good radiograph was of value for future information from a forensic standpoint, but no radiograph, in his opinion, should be admitted as evidence in any medico-legal dispute, unless both parties to the dispute knew the conditions under which the radidograph was taken.

Dr. L. L. McArthur said the *x*-ray was of immense importance to the surgeon from a forensic standpoint. He urged that the surgeon protect himself, whenever possible, by making an *x*-ray picture of a fracture after the limb had been put in the best possible position and condition, and submit it to the patient, telling him that that was the best position that could be obtained, and asking him if he was satisfied with it. In this way the surgeon allowed the patient to know that he had utilized every means in his power, and all the instruments of precision to accomplish a good result. The surgeon should impress upon the general practitioner and the laity that it was not essential for a good functional result to have actual anatomical reposition of the fractured ends.

Dr. J. W. Andrews said it was a revelation to him that several skiagraphs of the same case could show such a great difference. He concurred with Dr. McArthur that it was unnecessary to have absolute apposition of the fragments, yet the laity and some physicians, especially in the malpractice suits, felt that there must be absolute apposition, and that union must take place in that position; hence there was a growing tendency on the part of the laity to have fractures examined by some one with the *x*-ray after healing had occurred, and unless the result was a perfect one, there were threats of a malpractice suit.

Dr. C. E. Ruth said a number of malpractice suits emanated as the result of fractures, in which the basis of the proceeding had been the supposed findings from skiagraphs. He would dislike very much to treat a case of fracture without having taken skiagraphs, or having made fluoroscopic examinations of the limb in different positions. The surgeon should be careful not to tell any patient that he would get a perfect result.

Dr. A. I. Bouffleur stated that as a confirmatory measure the *x*-ray was of great value, but as a substitute for ordinary means, it was, in his opinion, not proper to place the reliance on it which he had heard at different times concerning it.

Dr. M. L. Harris said the Association should not go on record as supporting the statement that in the treatment of fractures the *x*-ray should be used. He did not think it was a necessary means of diagnosis. In nine cases out of ten it was not only unnecessary, but it did not furnish the surgeon with any information which could not be obtained in other ways. He admitted its value in showing something which one could not detect in any other way. He pointed out the fallacies of the *x*-ray. It was impossible in many instances for anyone to interpret correctly an *x*-ray picture. Skiagraphs should never be admitted as evidence in a medico-legal contest.

Dr. A. E. Benjamin said it was well to employ the *x*-ray as an additional confirmatory aid in the treatment of fractures.

Tin Splints.—Dr. Arthur T. Mann of Minneapolis, Minn., made a plea for the general utility of tin splints. He pointed out the simple equipment necessary to make them; also the ease of making the splints and patterns for them. He described several tin appliances which were useful to the surgeon, and among them a device for regaining flexion and extension of the elbow joint after fractures and dislocations. He also exhibited a device for the protection of the line of sutures in operative cases of cleft palate.

Syncytioma Malignum.—Dr. H. C. Crowell of Kansas City reported a case of this comparatively rare disease, which was accompanied by a detailed pathological report of the specimen removed. He referred briefly to other cases which he had found in the literature.

Dr. Archibald Mac Laren reported a case of what he had supposed, from the history, to be a soft edematous fibroid, which came on five months after delivery. Probably there was no growth present until after the birth of the child. There was no extension beyond the wall of the uterus. The fundus was diffusely infiltrated with this peculiar fungous mass. Sections of the mass were examined by a competent pathologist, and a diagnosis made of syncytioma malignum. The uterus was removed above the internal os, in the belief that it was simply an edematous fibroid, and the case was treated like any ordinary supravaginal amputation. The woman at the present time had had no return of the disease, and there was no extension apparently to the lymphatics or neighboring tissues. A year had elapsed since the operation was done.

Fractures of the Tarsal Bones.—Dr. Daniel N. Eisendrath of Chicago called attention to the surgical anatomy of these bones, and the mechanism of fractures. He spoke of compression fractures; fractures of the neck of the astragalus following sudden dorsal flexion of the foot; fractures of both astragalus and calcaneus following forced supination or pronation of the foot; fractures of the astragalus which resulted from forcible action of the muscles of the calf; crushing fractures, and gunshot fractures. He discussed the symptoms and diagnosis together. In considering the treatment, he reported six interesting cases, after which he drew the following conclusions: "(1) The astragalus and os calcis bear the entire weight of the body. (2) They are most frequently broken in falls from a height directly upon the feet (compression variety), or by tearing off a portion of one of the bones either when the heel is fixed on sudden supination or pronation, or in forcible dorsal flexion of the foot. (3) Early diagnosis, on account of the danger of sepsis from secondary skin necrosis, is of great importance. (4) If there is no displacement of fragments, treat the case by a cast for six weeks, with early massage. If displacement threatens

necrosis of skin, convert into open fracture, and remove the fragment or suture it."

Ptosis of the Abdominal and Pelvic Organs.—Dr. R. C. Coffee of Portland, Oregon, read a paper on this subject, which was accompanied by numerous illustrations. He said that the peritoneum was attached to the diaphragm, and by all its outer surface to the abdominal and pelvic walls by means of loose connective tissue, which allowed it to move freely, but held it always in contact. This connective tissue was much increased around the attachment of the supports of each organ. The peritoneum itself was but slightly elastic, its seeming elasticity being due to the elasticity of the subperitoneal connective tissue. Two peritoneal surfaces brought together and held firmly in an aseptic state would blend and become one membrane. In the case of suppuration blending did not take place, but inflammatory adhesions were formed. The former condition was permanent, while the latter was transitory, the adhesions being absorbed generally. This differentiation was all-important. The uterus was suspended entirely by its peritoneum and connective tissue. The so-called true ligaments were not true ligaments, but muscles. Their function was to sustain the normal poise or balance of the uterus during the changing positions of the body. Whatever the cause, ptosis was a stretching of the peritoneum or connective tissue, either or both. The condition might be local or general, and might involve the support of one, more than one, or all the abdominal pelvic organs. The treatment of ptosis in general was the shortening of the peritoneum at the points at fault by some method of plication and blending, or by bringing the peritoneum back to its normal contact with the abdominal wall. He described a method for suspending the liver by shortening the normal suspensory ligament, and supplementing it by extending the ligament to one or both lobes by blending of peritoneum. He said that none of the operations for gastroptosis was either theoretically or practically ideal for all cases. The hammock operation, stitching the omentum to the abdominal wall, was best suited to those cases due to adhesions holding the stomach out of place by its omentum. Posterior gastroenterostomy was the best operation for those cases due to dilatation or pyloric obstruction of any kind.

Appendicitis in Women.—Dr. Archibald Mac Laren of St. Paul, Minn., said that in the light of recent experiences, he believed the only safe advice both to the patient and the physician was that the appendix should be immediately removed in the early hours of every acute attack of appendicitis, and especially in first attacks, when the symptoms lasted six hours. On the other hand, he did not believe that every case of appendicitis should be operated upon as soon as the diagnosis was made, because the surgeon frequently did not see these cases until from the third to the sixth day. The favorable time had now passed, and, as Richardson had said, some of these cases were in such a bad condition that the operation itself might be enough to take away the only remaining chance of recovery. He had made 422 appendectomies. In the first 241 there were 72 suppurative cases. Of these there were 42 men and 30 women, in spite of the fact that his work was largely the surgery of women. During the same time he had removed appendices showing chronic inflammatory changes 153 times in women and only 17 times in men. He did not quote these figures for the purpose of giving the impression that they fulfilled his idea of the true relationship of chronic appendicitis in the sexes. He did not believe that chronic appendicitis was as frequent in men as in women, but it probably was not twice as frequent in the latter. It was, he believed, only a curious accident that he had seen proportionately so many acute cases in men and so very few chronic cases.

Management of Hospitals in Cities of One Hundred Thousand Population or Less.—Dr. D. S. Fairchild of Des Moines, Iowa, stated that the problems involved in the management of hospitals in the smaller cities were difficult and complicated, growing out of two important facts; first, the supposed self-interest of individual members of the medical profession, and, second, the lack of experience and knowledge on the part of boards of management. Public hospitals were generally of three kinds, as determined by the auspices under which they were organized and in part supported: (a) Hospitals under the auspices of some church; (b) hospitals under the auspices of some society, and (c) city hospitals supported by public taxation. The method of appointment of physicians to hospitals was liable to abuse only when piety or church zeal was mistaken for competency. The author discussed the management of hospitals at great length.

Arthrotomy.—Dr. E. Wyllys Andrews of Chicago described a new method of arthrotomy for old dislocations of the shoulder joint, and after mentioning the steps of the procedure at considerable length, he presented the following conclusions: "(1) It must be considered established that great force is never justifiable in old shoulder dislocations. (2) Few cases can be left unreduced, on account of pain and pressure symptoms on the brachial plexus. (3) Resection is satisfactory, but not ideal or wholly safe. (4) Arthrotomy by the old incisions is tedious, and never has been widely practised. (5) Arthrotomy by the author's method is simplified, and made quicker and safer. It would possibly be as safe as resection, and much more ideal in results."

Curettage and Puerperal Sepsis.—Dr. C. E. Ruth of Keokuk, Iowa, discussed the etiology of puerperal sepsis, the kinds of infection, prevention, dangers, as well as curettage, drainage, and hysterectomy in such cases.

Our Duty to the United States Army and Its Medical Corps.—Dr. Donald Macrae, Jr., of Council Bluffs, Iowa, pointed out the importance of having a more efficient medical corps in the United States army. He made an appeal to the patriotic sense of the American surgeon in civil practice to stand by the recommendations of the Surgeon-General of the army, and otherwise to use his best endeavors to relieve a most deplorable condition in the most important branch of the service. He thought that the Surgeon-General should be elevated to Lieutenant-General, and be equal in rank to the head of any other branch of the army. A medical officer should be added to the general staff.

A resolution was introduced and unanimously adopted respectfully petitioning President Roosevelt to direct that the military authorities provide a field medical organization for our army at least equal in all respects to the best that exists in any army, and which would meet the approval of military sanitarians generally, to the end that the sick and wounded in future wars might receive adequate care and attention. The secretary was instructed to forward a copy of this resolution to President Roosevelt at once.

Removal of the Covering of the Ovaries in Ovarian Dysmenorrhea.—Dr. George G. Eitel of Minneapolis, Minn., presented a preliminary study on this subject, and described the technique of the operation he had performed in seven cases, as follows: "The ovary is brought into clear view through a median abdominal incision; one hemostatic forceps is placed at the juncture of the utero-ovarian ligament and ovary and another on the upper border of the broad ligament close to the ovary (lateral). By means of these two forceps the ovary is held by an assistant in the proper position, while the operator makes an incision with a sharp scalpel from the utero-ovarian ligament to the lateral attachment to the broad ligament through the covering, and then carefully dissects one side and then the other, down as far as cysts are encountered. The flaps of the covering of the ovary are now trimmed off, preferably by means of a pair of scissors. This having been done, the utero-ovarian ligament is shortened by doubling it upon itself in a similar manner as is in vogue in shortening the round ligaments, in order to hold the uterus in a normal position. There is generally some hemorrhage as the base of the ovary is encroached upon,

which can easily be controlled by pressure forceps and fine ligatures."

Diagnosis of Early Tubal Pregnancy.—Dr. William E. Ground of Superior, Wis., after going into the diagnosis exhaustively, and quoting from the literature, stated that during the last year he had operated upon ten cases of tubal pregnancy. He had operated upon twenty-eight cases altogether. His deductions were based on the histories and the gross appearance of the uterus and appendages at the time of operation. He was firmly convinced that some lesion was always present to cause the arrest of the fecundated ovum in the tube. Five of his cases were in primiparæ, who gave a history of painful menstruation and leucorrhea. Thirteen cases gave a history of a prolonged period of sterility; by this he meant three years or longer. The remaining twelve cases occurred in parous women, who had borne children or had been pregnant within less than three years. Many of these women gave unmistakable evidence of preexisting pelvic disease. One primipara had been married three years, one five, and another eleven years, before tubal conception occurred. Two cases occurred in unmarried women, one of whom had had a criminal abortion produced. Complications arose, and she was sent to the speaker for abdominal section, when an unruptured tube containing a six weeks' fetus was found. In another case, a woman living apart from her husband was known to have had chronic appendicitis; she was taken with a sudden severe pain in the right lower abdomen, followed by considerable shock, but soon rallied and had a slight fever. At this juncture the speaker saw her. Menstrual irregularities were denied. Tenderness was present rather low in the iliac fossa for appendicitis, the uterus was enlarged, and a slight bloody discharge came from the vagina. There was an ill-defined tumor to the right of the uterus. The abdomen was opened, and found to contain blood clots and bloody serum. The right tube was ruptured on its dorsum, at about the middle, but the fetus was still in the tube. Chronic appendicitis was also present, and the appendix was removed. Two of the patients had small fibroids, and one had an ovarian cyst as large as an orange on the opposite side.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. H. D. Niles, Salt Lake City, Utah; *Vice-Presidents,* Drs. E. Wyllys Andrews, Chicago, and W. W. Grant, Denver, Colo.; *Secretary-Treasurer,* Dr. B. B. Davis, Omaha, Neb.

Kansas City, Missouri, was selected as the place for the next meeting, with Dr. H. C. Crowell as Chairman of the Committee of Arrangements.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held December 8, 1904.

Dr. David Bovaird, Jr., Chairman.

Rachitic Fracture of Femora, with Radiograph.—Dr. L. E. LaFetra presented this patient, a rachitic child, with fracture of the femora at the middle. The particular interest in the case was the difficulty of diagnosis. When first seen by him the child could not sit or stand without support. Rachitic symptoms were present—sweating of the head, bowing of the humeri and the radii, protrusion of tongue, enlarged spleen and liver, hyperplasia of inguinal and epitrochlear glands, etc. There was also angular deformity of the femora with the convexity outwards, with some swelling of the shaft at the middle on each side. Syphilis and scurvy were both thought of, but a careful examination of the femora showed that the tenderness was at the middle of the shaft and not at the epiphysis, where it would be if the condition was syphilis or scurvy. The child was in such bad condition physically that no attempt was made to correct the deformities, although the baby had improved very markedly under treatment. The deformity was quite misleading in that it resembled the anteroexternal deformity of rachitis. If it had not been for the tenderness over the seat of fracture this diagnosis would not have been made in all probability.

Treatment of Erythema Induratum (Scrofuloderma).—Dr. L. E. LaFetra presented this patient, a boy, whom he first saw in June, 1903, when he was two years of age. The child was presented to show the marked improvement that had taken place under treatment. The brief history of the case was as follows: The mother had had one miscarriage. One uncle had died of tuberculosis but had never lived in the same house with the child. The child was circumcised and then began to have swelling of the midphalanx of the fourth finger of the left hand; this increased greatly and then diminished. In December, 1902, a bluish spot appeared on the side of the face and then on the other side; both spots were deeply indurated, freely movable subcutaneously, and could be better felt than seen. After a few days a lump appeared under the left ear, and there then followed enlarged cervical glands. There were no night sweats and no fever. The physical examination at the time of the first visit (June, 1903) revealed a small elevated mass in the skin on the inner aspect of the right forearm and of the left hand. The localization of other spots was referred to, near the patella, the right calf the size of a lentil, the left leg, over from the thigh, sole of right foot, outer side of left buttocks, etc. The liver and spleen were slightly enlarged. Guaiacol was given in two-minim doses twice a day, and cod-liver oil. The daktylitis opened and discharged; some of the pus was taken and examined for tubercle bacilli, but none was found. Great improvement occurred in the general condition of the child. The nodules in the skin began to diminish in size, and now most of them were hardly discoverable. A nodule from the left hand was incised and examined, and a few tubercle bacilli were found along with a cheesy mass in the center. During February, 1904, the little boy had measles, followed by lobar pneumonia, and he made a satisfactory recovery without a trace of the disease being left in the lungs. This was interesting, because it was well known how much measles and pneumonia predisposed one to tuberculosis. This child had tuberculosis all over the body surface, and had measles which was followed by lobar pneumonia, and still he did not present a trace of anything in the lungs at present time. There was also an absence of general glandular involvement.

Dr. Jacob Sobel said he had never seen such a case in a child so young. The location upon the lower half of the leg and posteriorly was also rather unusual. If the condition was diagnosed early before any ulceration had occurred the chances for improvement were more marked than if the diagnosis had been a late one.

Dr. David Bovaird, Jr., said that he left school with the impression that such cases were always syphilitic, but nearly all the instances that he had since seen were tuberculous.

A Case of Cephalocele Occipitalis Inferior.—Dr. Sara Welt-Kakels presented this case. The patient was nine months old, breast fed, and was brought to her office some three weeks ago on account of a tumor on the occiput. Her parents were healthy. There were five children and two were still born, in the eighth and ninth month of pregnancy. Two were living and well. The last child, the one presented, was born at full term with an easy delivery. The child was cyanosed at birth, breathed very feebly, and did not cry until about fifteen minutes after birth. The tumor was noticed at birth, but had not grown since. The baby had always been ill and very restless. Last summer she suffered about two months from whooping cough. Previous to the time Dr. Welt-Kakels saw her she had diarrhœa and vomiting and was so weak she could not hold her head up, did not appear to recognize her mother, and had no teeth. The child's present condition was: weight, eleven and one-half pounds, very poorly fed, listless, organs of chest and abdomen normal, thymus dullness present, liver slightly enlarged, spleen easily palpable,

urine free from albumin and sugar, and, in the occipital region, a tumor, soft, compressible, translucent, covered by normal skin; when the child cried the tumor increased. The tumor was not sensitive to pressure and could be completely reduced without any cerebral symptoms resulting. After reduction an opening in the skull could be made out which seemed to communicate with the foramen magnum. Examination with the *x*-ray revealed a slight shadow which could be caused by the presence of brain substance. The old division of these tumors was into meningocele, a protrusilon of the meninges; encephalocele, a protrusion of the brain substance; and hydrencephalocele, protrusion of a portion of brain substance, containing in its interior a cavity filled with fluid, which communicated with the distended lateral ventricles. The origin of these malformations was dependent upon a faulty closure of the cerebrospinal tube. This took place about the second week of fetal life, when the human embyro measured about two to three mm. in length. In some cases amniotic adhesions would be responsible for this defective state of the skull. The prognosis was very bad; according to the statistics obtained by one man out of 199 patients with encephalocele only seven reached adult age, and Miller was quoted reporting thirty-nine foundlings with encephalocele who died before the end of the first year. On the other hand, the results of surgery had been much better and one individual had collected reports of sixty-three patients who were operated upon, with thirty-three recoveries; while still another individual reported but two deaths out of ten nurslings operated upon for this malformation.

Demonstration of a Method of Obtaining Urine from a Female Infant.—Dr. Sara Welt-Kakels gave this demonstration, using for the purpose a bottle and a strip of adhesive plaster.

Remarkable Mental Improvement Following Operation for Depressed Fracture of the Skull.—Dr. B. V. D. Hei[illegible] of Plainfield, N. J., reported this case, to be published later.

Hypertrophy and Stenosis of the Pylorus in Infants.—Dr. F. L. Wachenheim read this paper. He reported the case of an infant aged five weeks, breast fed, who had had uncontrollable vomiting after the second week; the condition of the bowels varied from constipation to moderate diarrhœa with green stools. Examination of the child revealed nothing but extreme loss of flesh and strength. Albumen water and ordinary barley water were vomited within twenty to thirty minutes, the vomiting being forcible. Very dilute barley water and lime water were retained usually, but not invariably. Five days' observation led him to suspect a hypertrophic stenosis of the pylorus, though the stools led him to suspect a catarrhal condition of the stomach. The child died at the age of seven weeks. Autopsy showed enlargement and moderate congestion of the liver and spleen, the former overlapping the pyloric region; under it the almost cartilaginous mass of the pylorus could be palpated. Not counting the pyloric end the stomach had an extreme length of 10 cm., distended with air and gelatinous fluid, the walls tense and of about normal thickness. The pyloric end of the stomach was 3 cm. in length, and so thick and firm as to appear like a new growth, projecting into the duodenum like a cervix uteri; its diameter was 14 mm., while that of the duodenum was only 8 mm. The walls of the pylorus had a thickness of 6 mm., and evidently consisted chiefly of muscle, though there was a thickening of the submucous connective tissue. The mucous membrane appeared perfectly normal, but was thrown into longitudinal folds. The result of the autopsy was a positive finding of hypertrophy and stenosis of the pylorus. Only about sixty cases of this condition, he said, had been reported. Clinically and pathologically these cases of hypertrophy and stenosis of the pylorus in infants might be divided into three groups. First, those that attained an age beyond infancy, presenting throughout their lives more or less obstructive symptoms, unless they sought operative relief. Here the stenosis must be of moderate degree, the pylorus measuring five mm. or upward. Secondly, those infants which presented during some weeks similar symptoms which gradually disappeared under medication and diet. Thirdly, those babies which were either promptly relieved of an almost total obturation by surgical means or who died within a few weeks. The paper was confined chiefly to a consideration of the third group. From the moderate number of cases that had come to autopsy he deduced a clinical picture. The average age at onset was two weeks, the average age at death nine weeks and one-half; it might safely be decided that every case surviving beyond four months did not belong to this clinical group. Males dominated in the ratio of two and one-half to one. Almost all the infants were breast fed, thus eliminating improper food as a causative factor. The intensity and frequency of vomiting were directly proportional to the quantity and consistency of the ingesta. In a number of cases pure water or thin barley water was retained, while food forming semisolid masses in the stomach was ejected. The acidity in the vomited matter was not always due to free hydrochloric acid; biliary vomiting was not so very rare, and was a symptom that would not be expected. This symptom as well as diarrhœa and green stools gave rise to diagnostic doubts. It often required a week or more of observation before one could make a diagnosis, and, indeed, most cases remained unrecognized and unreported, being passed by as gastrointestinal catarrh. The palpation of the hypertrophied pylorus was an uncertain quantity and was rendered difficult or impossible by the constant crying of the infant. Visible peristalsis and dilatation of the stomach were usually noted only when that organ was well filled; sometimes only in the terminal stages of the disease, and often not at all. In view of the usual designation of this affection as congenital it was curious that most of the cases showed no symptoms during the first week or two, the onset usually being quite abrupt, and from these circumstances the question of the pathogenesis was difficult to answer and clinicians held views diametrically opposed. Still was convinced that the chief element in this disease was spasm, that hypertrophy was secondary and not of a high degree, that the relatively short duration of the affection admitted of only moderate muscular overgrowth, that serious and permanent changes were inconsistent with the reported cures, and that the narrowing of the pyloric lumen as found post mortem, was often very moderate. Other authorities considered the lesion wholly anatomical. Again others were prepared to accept both propositions. They believed that there was one condition that consisted in an overgrowth of the muscular and submucous coats of the pylorus, aggravated by a tonic contraction which, in all probability, was due to the abnormal innervation that usually accompanied muscular hypertrophy. They could also admit a pyloric spasm pure and simple, possibly accompanied by some slight muscular hypertrophy. It was evident that the prognosis of the first condition was bad, and of the second fairly good. A combination of moderate primary hypertrophy and stenosis with spasm was possible. Still and Pfaundler had made valuable contributions to our knowledge of the dimensions of the normal infant pylorus. Still stated that the average thickness of the organ was 2.5 mm. with an absolute maximum of 3.3 mm. in infants of about six months. Pfaundler set the lumen at birth at 6.3 mm., and 8.5 at six months. According to both, a lumen of 5 mm. at two or three months could hardly amount to a serious obstruction. When the pyloric lumen measured less than 3 mm. the attendant spasm of the hypertrophied muscle seemed sufficient to cause almost complete and permanent closure, absolute, however, in not a single recorded case. The histological findings in his case showed nothing abnormal in the mucosa and its glands. The submucosa was about twice the normal thickness, with considerable round-cell infiltration. The muscular coats were enormously hypertrophied; the circular coat had from four to five times the

muscles was proportionately nearly as great. In the muscular coats there was a moderate amount of inflammatory reaction. There was no change in the blood vessels out of proportion to the excessive development of other tissues. The reader of the paper was of the opinion that the rarity of the disease had been exaggerated, as the diagnosis was by no means easy, especially in the summer, when there might be a combination of pyloric stricture with digestive disturbance. The keynote to the diagnosis of this affection was the combination of obstinate vomiting with equally obstinate constipation, and gradual loss of weight. In the vomiting, important points were its violence and its close dependence on the ingestion of food. The appetite was above normal; a combination that could hardly occur in any other disease. As it was impossible at once to tell whether spasm or organic obstruction was playing the chief rôle, and since operative intervention was attended by a high mortality, it was well to begin by assuming the milder condition, and to treat accordingly. Freund seemed to have had good results by giving Carlsbad water with the usual diet, breast milk, and later on whole milk. Some benefit seemed also to be derived from lavage. Small and frequent meals of highly diluted albumen water and barley water were also recommended. It was an error to continue this treatment beyond two weeks unless the infant increased in strength and weight, as further than this normal thickness, and the overgrowth of the longitudinal all treatment must be surgical. He gave a summary of cases in which operative procedures had been employed, which showed that in fifteen cases in which gastroenterostomy (suture) was done six were cured and nine were fatal; one case of gastroenterostomy (Murphy) was fatal; four cases of pyloroplasty resulted in two cures and two fatalities; three cases in which divulsion was performed resulted in two cures and one fatality. This gave a total mortality of 57 per cent., and it was probable that these figures were too favorable. The summary seemed to show about equally good results from all procedures, even from the Murphy button, which had not had a fair trial.

Dr. Robert T. Morris said it was noteworthy that Americans had contributed a very small number of these cases to literature, and he believes these cases were more common than supposed.

Dr. John Dorning said there was no question regarding the difficulty in making a diagnosis of these cases of pyloric obstruction in infants. Great difficulty was encountered in palpating the abdominal contents when the baby cried, unless it was much emaciated and very apathetic, when the abdomen would be found to be somewhat relaxed. When much resistance was encountered by the palpating fingers, he said he failed to see how harm could result from a few whiffs of chloroform, and he had given this in hundreds of cases of obscure abdominal affections, and without any untoward results.

Very little was known regarding gastroenterostomies in infants, and their results, and he believed very little could be said regarding the results of these operations, unless the cases were followed for months, perhaps years. We did not know either why an artificial opening made in the stomach would contract and become obliterated. In some cases this contraction of the gastric mucous membrane, but not of the intestinal, would result fatally.

Dr. Roland G. Freeman emphasized the statement that many of these cases were undoubtedly overlooked, and also that many cases reported were not really cases of stenosis at all. In many instances this simple thickening of the gut was very deceptive, and he had seen at least one case in which there was no thickening to be found in the specimen.

Dr. Wachenheim said that pains were taken to exclude doubtful cases, and there were as many as twenty or thirty of them; no cases were accepted without autopsy. It was difficult to give a border line between normal and pathological thickenings.

Philadelphia County Medical Society.

At a stated meeting held December 14, Dr. Brooke M. Anspach read a paper entitled "The Differential Diagnosis and Treatment of Acute Pelvic Peritonitis of Gonorrheal Origin." He stated that gonococcal peritonitis is usually confined to the pelvis, and that even when generalized, the prognosis is comparatively favorable. The disorder may cause permanent disability and chronic invalidism, but rarely a fatal result. At times it bears a close clinical resemblance to appendicitis. In the one condition, however, symptoms of leucorrhea or vesical irritability have appeared soon after marriage or suspicious intercourse, while in the other there is a history of previous attacks; the one sets in at or directly after a menstrual period, the other after some indiscretion in diet; the one is attended with pain in the lower abdomen, worse, perhaps, on one or the other side, the other with pain at first in the epigastrium, and later localized in the region of the appendix; both may be attended with nausea, vomiting, and constipation, which are, however, likely to be more marked in cases of appendicitis. A correct diagnosis is important, because appendicitis, especially if complicated by peritonitis, should be subjected to early operation, while pelvic peritonitis of gonorrheal origin should be treated by means of rest in bed, copious douches of hot salt solution, applications of heat to the abdomen, and the administration of saline laxatives. Operation during the acute attack appears unwarranted in the latter form of peritonitis. Should, however, the inflammation of the peritoneum become general, immediate celiotomy is indicated. If on opening the abdomen a collection of fluid be found, this should be evacuated, no attempt being made to remove fibrinous deposits on the bowel, or to separate adhesions. If the diseased tubes contain appreciable amounts of pus, they should be removed. If, after expectant treatment, gross inflammatory alterations are discovered about the adnexa, operative interference becomes justified.

Dr. Robert H. Chase read a paper entitled "The Significance of Abulic Symptoms in Cases of Mental Disease." He stated that abulia, or a weakening or diminution of the will-force of the individual, finds expression in hesitation, indecision, and in many forms of powerlessness, as well as in defective energy of attention. It is observed normally in the inertia of convalescence, and in the lassitude of spring time; abnormally in various forms of mental and nervous disease. Abulia may be systematized, localized, or general. It must not be confounded with amnesia. Aprosexia is a condition of lessened power of voluntary attention.

Dr. T. Horace Evans read a paper entitled "The Advisability of a National Department of Public Health, and a Medical Cabinet Officer." He spoke of the intimate relationship between disease and the prevalence of crime, and he claimed the right of Medicine in government to control every matter concerning the physiological being of the citizen. The boundaries of social conduct may be defined by law, but once apprehended, the subsequent treatment of the criminal should fall within the domain of medicine. Marriage and education also are matters that come within the sphere of activity of the physician, as are likewise the questions of the proper training and licensing of practitioners of medicine and surgery, and the care of contagious diseases, and of the sick poor generally. Mental and moral defectives require the supervision of the State, and their restraint in suitable colonies is a means of greatly reducing crime. For the accomplishment of the foregoing ends, a national department of public health is necessary.

Result of Exposure to Radium.—According to Dr. Roux of Paris, mice which had been exposed continuously for twenty days to radium lost their hair. The hair subsequently returned, but was quite white. Mice exposed for longer periods developed muscular paralysis.

Pathological Society of Philadelphia.

At a stated meeting held December 22, Drs. M. P. Ravenel and C. A. Fife presented a communication entitled "Tuberculosis of the Peritoneum," and showed specimens from the body of a child two years old that had died of tuberculosis of the mesenteric glands, to which apparently the inflammation of the peritoneum was secondary and giving rise to the formation of an intraabdominal mass of considerable size binding loops of intestine intimately together. There was no tuberculous involvement of the lungs, which exhibited the lesions of bronchopneumonia, and it was impossible to determine with certainty whether the mucous membrane of the bowel was involved. The child had been fed on milk obtained from doubtful sources. Histological examination of the tissue disclosed the lesions of tuberculosis, with the presence of tubercle bacilli; and organisms presenting characteristics conforming with those of the bovine tubercle bacillus were obtained on culture. The case thus appears to be clearly one more of those in which infection took place by way of the intestinal tract, probably through the medium of contaminated milk, as tubercle bacilli have been found in a number of specimens of market milk examined with this point in view.

Drs. Leonard Pearson and S. H. Gilliland presented a communication entitled "The Effect of Tuberculosis Vaccination Upon Tuberculous Cattle." Of twelve calves, the offspring of members of a tuberculous herd, six were used as controls, three were treated with intravenous injections of non-virulent tubercle bacilli and the remaining three with similar injections in alternation with occasional subcutaneous injections of tuberculin. Of these three groups the results were worst in the controls, less bad in those treated with injections of tuberculin only, and best in those treated jointly with tubercle bacilli and tuberculin.

Dr. Warfield T. Longcope presented a communication entitled "A Study of the Bone-marrow in Typhoid Fever and Other Acute Infections." He described at some length the changes that took place, especially in the leucocytes, in both red and yellow marrow, as compared with the conditions present in normal marrow.

Dr. W. B. Cadwallader read a paper entitled "Basophilic Granulations of the Red Cells in Lead-poisoning and Other Conditions, with Special Reference to the Nuclear Origin of the Granules."

Dr. H. R. Alburger exhibited a specimen showing "A Nail in the Vermiform Appendix." During life there had been little indication of the existence of such a condition and anatomically there was no evidence of inflammation of the appendix.

Dr. George S. Crampton demonstrated blood from a case of "Filariasis." The patient was a colored man, who had lived most of his life in Charleston, S. C., and who, form time to time, passed milky urine. He knew of a comrade who exhibited the same peculiarity and examination of the blood in both instances disclosed the presence of filariæ.

Dr. Robert N. Willson, Jr., exhibited a consolidated lung from a patient in whom during life percussion had yielded the signs of a cavity; and also the heart of a colored woman with a history of syphilis, which showed mitral and tricuspid obstruction.

Dr. H. E. Wetherill exhibited a color scale for the determination of hemoglobin percentages by daylight and a hematokrit operated on the principle of the whirligig.

Chicago Medical Society.

The subject of "Pneumonia" was discussed in its various aspects at a meeting held December 14. Dr. C. S. Williamson read a paper on the "Onset in Pneumonia, Typical and Atypical." The author stated that pneumonia frequently began with sharp abdominal pains, and this fact was first impressed upon him by observing a distinguished surgeon operate upon a case for supposed salpingitis, because of intense pain in the lower abdomen. The patient died within twelve hours, and autopsy revealed no abdominal or pelvic disease, but a double croupous pneumonia. The commonest group of these abdominal cases embraced those in which the pain and tenderness were localized at McBurney's point for the first two or three days—the appendicular form. The author agreed with Massalongo as to the frequency of this form in childhood. In other cases the pain was localized to the gall-bladder region, and might mimic biliary or even renal colic, or gastric ulcer for the first twenty-four or thirty-six hours. It was not justifiable to recognize separate groups of cases in acordance with the localization of the pain at the onset. He called attention to the fact that the onset in old people was apt to be entirely latent. In some cases there was a chill, with but very slight elevation of temperature. A chill occurring in old people without apparent cause should be always regarded as suspicious of pneumonia. In the terminal pneumonias, the onset, frequently the entire course, was latent. In alcoholics the same statements would apply. A small proportion of cases of croupous pneumonia were due to the pneumobacillus of Friedlander. The clinical symptoms did not ordinarily differ from those of cases caused by the pneumococcus except in one important point, namely, in regard to the character of the sputum. In the Friedlander pneumonia, the sputum was so characteristic that from it alone a fair diagnosis of the form of pneumonia might often be made. It was intensely mucoid, ropy, and strong, and when lifted upon a knife blade or similar instrument it could be drawn out in long threads. This was a point which had hitherto escaped general observation. Attention was directed to the fact that the Friedlander pneumonia might be readily recognized post mortem by observing the character of the cut surface. This, instead of being dry, as in the pneumococcus form, was bathed with a ropy, tenacious, rusty-looking mucus, which was highly characteristic of cases produced by the pneumobacillus. Very much rarer than the above cases, but more important, were the cases where the onset was with a pneumococcus septicemia. The author quoted a case seen by him in consultation, where the onset was with a bloody discharge from the nasopharynx and middle ear (through an old perforation in the drum), and where the lung findings were entirely negative. Examination showed a nearly pure culture of pneumococci in the bloody serum from the nasopharynx and the ear; the cultures from the blood revealed the pneumococcus in pure culture. Twenty-four hours later a pneumonia developed. In this case the march of events was undoubtedly that the infection occurred from the nasopharynx and ear, from which sources bacteria were taken into the blood to produce, several days later, a croupous pneumonia.

Dr. Robert H. Babcock contributed a paper on "The Physical Basis for Diagnosis in Pneumonia." He stated that the pulmonary findings on which the diagnosis of acute coupous pneumonia might be based were determined by the pathological conditions within the lung, and as this latter varied much in extent and in character, during the different stages of the process, the physical signs displayed corresponding differences in definiteness and character. After laying down three propositions, which the author regarded as fundamental to a correct understanding of the data furnished by examination of the chest in this affection, and discussing the state of engorgement, the stage of hepatization, mensuration, palpation, percussion, auscultation, and the microscopical examination, Dr. Babcock related a case, recently seen in consultation, of a man, 60 years of age, who was suffering from cardiac insufficiency. He had been having a cough of chronic bronchitis and two weeks ago was edematous. Treatment had improved his condition, but the last three days he had been slightly delirious. He found a heart lesion, to be sure, but the pulse was only 96, and signs of stasis were not present. The thing that impressed him at once was the character of

the respirations, which were shallow and forty to the minute. Mouth temperature was normal, but in the rectum the thermometer registered 103° F. The lungs were then carefully examined, with the result that on the left posterior axillary line, not far from the scapula, was discovered a small patch of dullness, with increased resistance, slightly exaggerated tactile fremitus, and bronchial breathing. Of these findings a diagnosis of pneumonia was made. Without the loss of normal pulse respiration ratio he would not have suspected acute pneumonia, but with this and the rectal temperature he was led to go over the lungs with more than ordinary care, and with the result just stated.

Dr. Arthur R. Elliott followed with a paper on "The Cardiac and Renal Aspects of Pneumonia." Among other things, he pointed out that on the heart and kidneys rested the safety of the pneumonia invalid. Owing to special conditions imposed by the disease, circulatory considerations took precedence of all others in importance. General agreement existed that cardiac insufficiency was the usual cause of death. The author distinguished between symptomatic involvement of the heart and inflammatory lesions of the cardiac structure occurring as complications, and restricted himself to a discussion of the former. Three forms of cardiac failure were observed in pneumonia, viz., collapse with a high temperature, collapse occurring at the time of crisis or soon after, and collapse following exertion during convalescence. Various explanations have been advanced to account for the cardiac collapse in pneumonia. The author proceeded to discuss the various theories, taking up serially the ideas of von Jürgensen regarding the importance of pyrexia in bringing about circulatory crises, the importance of the direct action of pneumococcus toxins in the production of cardiac asthenia, the effect upon the heart of the obstruction of the pulmonic circulation in causing right heart paralysis, and the vascular theories of Romberg and Passler and Rolly. Blood pressure observations in pneumonia were analyzed, and the author concluded that heart failure was probably due to several causes, the principal of which were vasomotor paresis, paralyzing distention of the right heart, and the direct action of toxins on the myocardium. The clinical signs of cardiac collapse were next reviewed, and attention was directed to the importance of studying the pulse and pulse respiration ratio in pneumonia. The renal aspects of pneumonia were discussed, regarding which but little information was current. Pneumonia complicating Bright's disease was frequent, but acute nephritis as a complication of pneumonia seldom occurred. One was not warranted by experience in ascribing to the pneumococcus any more important influence in the production of nephritis than was possessed by other infective organisms. Cloudy swelling and other slight degenerative changes were noted in the kidneys in the majority of cases of pneumonia examined, and more or less albuminuria was observed during the course of the disease and systematically tested for. Statistics showed the association of a high death rate, and albuminuria probably because of resulting renal inadequacy. From this standpoint albuminuria might be regarded as an unfavorable development. Pus, blood, and casts in the urine pointed to mycotic endocarditis or a local pneumococcus infection of the kidneys. Other urinary considerations were of less importance.

Sixty-One Meters of Tenia.—Chavigny reports this unusual case. The patient was a soldier (in the south of Algeria) became infected with tapeworms. On his return to France he underwent treatment by pelletierine with all of the usual precautions. In one morning the patient passed a remarkable quantity of these parasites. On examination of the fragments, there were found two complete tenias with the head; four fragments each belonging to a tenia, but without a head. In all, there was the part or the whole of six worms, and the entire length of the fragments expelled measured 61 meters. *Lyon Médical*, November 27, 1904.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 7, 1905:

	Cases.	Deaths.
Measles	122	11
Diphtheria and Croup	300	45
Scarlet Fever	227	22
Smallpox	.....	.....
Chickenpox	138	.....
Tuberculosis	282	108
Typhoid Fever	47	11
Cerebrospinal Meningitis	.....	24
Typhus Fever	.....	.....
Yellow Fever	.....	.....
Cholera	.....	.....
Totals	1,116	281

Calomel an Intestinal Antiseptic.—Alexander McAlister declares that calomel is the best antiseptic in pediatric practice. Unlike the so-called intestinal antiseptics, calomel does not interefere with the action of digestive ferments. It does not retard a single normal process, whether secretory or mechanical. On the other hand, it liberates the stagnant bile, increases the pancreatic secretion, and stimulates all the intestinal glands. The result is not merely the characteristic large watery calomel stool, but the restoration of functions which make for a normal intestinal flora. Bacterial activity is essential to normal digestion and assimilation. The presence of a powerful antiseptic in the intestines is injurious to that degree in which it is destructive to this normal flora. In conditions of excessive bacterial activity, the indications for treatment are always threefold; fecal accumulations must be removed, glandular activity stimulated, and the excess of bacteria reduced to the normal proportion. Calomel meets this threefold indication for treatment. The writer, as a rule, administers one-tenth grain doses every hour till one grain has been given, or till evacuations occur. If the condition treated is diarrheal, smaller doses are employed or the interval lengthened. The first object in treatment is to reduce abnormal bacterial activity. For this purpose the combination of sodium bicarbonate with calomel acts beneficially by facilitating the conversion of the insoluble chloride into soluble compounds.—*The Therapeutic Gazette.*

Histology of Roentgen Ulcers.—A. Gassmann exposed a rabbit daily to an intense *x*-ray and excised parts of the resulting ulcer at short intervals, to be examined microscopically, with the following results: In the specimens taken from the ulcer edge [illegible] could be found in the large vessels very marked and definite changes. There were present sieve-like perforations of the muscularis, thickening of the intima with perforations, and loosening of the elastic layer. As regards the partial thickening, the intima was not only split, but in places doubled and tripled, especially in the arteries (similar to that described in syphilitic endovasculitis). In the veins and larger lymph vessels, the thickening at times reached a stage of complete obliteration. Here, besides the spindle cells, there were more or fewer mononuclear and polynuclear leucocytes present. That is, there was an inflammation of the intima. It was difficult to determine how the loosening, especially of the smooth muscles, took place. The spaces were not intracellular, but pericellular. The most probable explanation points toward an œdema of the cells. They had in their swollen condition filled up a space which remained vacant on their hardening and retraction. Another possibility was that they were surrounded by a fluid exudate, which became absorbed. In this specimen there was also evident a marked degeneration of the cross-striped muscular fibers.—*Archiv fur Dermatologie und Syphilis.*

The Nature of Tabes and General Paralysis.—Leredde in his book on "The Syphilitic Nature and the Curability of Tabes and General Paralysis," speaks very strongly against Fournier's proposition that tabes and general paralysis are of a syphilitic origin, but not of a syphilitic nature. He is of a contrary opinion, and does not believe in the existence of "parasyphilitic manifestations," but looks upon all manifestations as specifically syphilitic. Tabes and paralysis he classifies as "tertiary atypical sclerotic syphilis." He refers to Renaut, who considers syphilis as a sclerosis produced by an endarteritis, which, according to Leredde, in tabes and paralysis, has affected the nervous system. As a further proof of his assertion, he refers to Nageotte, who claims that the meningitis in every case of tabes is syphilitic. The poor results derived from antisyphilitic treatment he believes due to the insufficiency of the mercury administered. Only pure mercury has the proper effect, and this is contained in varying quantities in the different preparations. Calomel contains the largest percentage. He prefers injections to inunctions. In tabes and paralysis we should begin with smaller doses than in other syphilitic nerve manifestations, and continue to increase the dose according to the reaction produced. If fever develops or loss of weight the drug should be discontinued for twenty-four hours and begun again in smaller doses. Leredde believes that with sufficient and properly regulated administration of mercury tabes and general paralysis are absolutely curable.—*Archiv. fur Dermatologie und Syphilis*

Action of Radium on Some Organisms.—H. H. Dixon and J. T. Wigham report on experiments made to determine the action of radium on growing seeds. The exposures were made to a tube containing 5 mg. of radium bromide. The effect was slight and consisted in a reduction in the rate of growth of those seeds within a distance of 1 cm. from the tube. "In one case a seed germinated immediately under the tube and the plant grew up in contact with it." In experimenting on various bacteria, such as pyocyaneous, prodigiosus, anthracis, and typhosus, they found a more marked effect. The tube containing the radium bromide was supported over the surface of the cultures as close to them as possible, and it was found that the organisms within a distance of 1 to 3 cm. from the tube failed to grow or were delayed. Three degrees of inhibition were observed: 1. Where the growth of bacteria was raped the radium simply retarded it. 2. In others, growth took place as soon as the radium was removed. 3. In the majority of cases in which normal growth took prolonged incubations free from the action of the radium tions. The radium did not seem to act by injuriously affecting the medium on which the cultures were growing, but by the actual inhibition of the bacteria themselves.—*The Dublin Journal of Medical Science.*

Improvements in Subcutaneous Hebotomy.—Döderlein adds four more successful hebotomies to the nineteen he has already published, and describes two radical improvements in the technique. In one case through inadvertence during the extraction, the thighs were separated to an unnecessary degree and a tear into the vagina resulted. To avoid this accident the author now counsels the application of a sterile rubber bandage about the pelvis before the operation is done, in order to prevent undue separation of the severed ends of the bone. In cases where it is possible that extraction may succeed without enlargement of the pelvic strait the author makes the incision and places the wire saw in position, but gives it in charge of an assistant. The extraction is then proceeded with and, if necessary, the bone can be divided in ten seconds, whereas if the delivery is effected without this measure the slight wound of the soft parts is of no consequence.—*Zentralblatt für Gynäkologie.*

The Rachitic Hand.—Henry Koplik calls attention to the peculiarities of the rachitic hand. He states that most of the children in whom the rachitic hand could be demonstrated suffered from marked rachitis, accompanied by pain in the bones to such a degree that one would be apt to think of syphilis. But the picture was so different from that of syphilis that the real nature of the disease could not be questioned. The changes occur in the shaft rather in the epiphyses of the phalanges. The middle of the diaphyses of the phalanges of both hands is bowed and thickened. A radiograph is shown in which it can be seen that the soft parts are free from undue thickness, the peculiar conformation of the fingers being due to thickening of the bones of the phalanges. The appearance of the hand is not caused by any fatty tissue which may be present in the fingers. The fingers of the hand are longer and more tapering than is usual in the hand of an infant of the same age. This seems to be due to a laxity of ligamentous structure of the joints of the phalanges. The distance between the extremities of the phalanges which make up the joints is greater in the rachitic than in the normal hand. This may account for the peculiar incurvated appearance of the fingers at the situation of the joints.—*Archives of Pediatrics.*

The Action of Milk on Blood Pressure.—Colombo describes experiments carried on in the laboratory of Dr. Mosso to determine the effect of the ingestion of large quantities of milk on blood pressure as registered by Mosso's sphygmomanometer. It was found that during the first few hours after taking, milk raises the blood pressure to a moderate degree and makes increased demands on the activity of the heart and respiratory organs. As soon as a certain degree of vascular tension has been reached diuresis and persistalsis are stimulated and the excess of fluid is excreted. The blood pressure now sinks suddenly, not only to the normal, but below it, and the pulse and respiration are also lowered. Therefore, the secondary effect is one of a diminution of blood pressure and of lessened work for heart and lungs.—*Zeitschrift für diätetische und physikalische Therapie.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plagle, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended January 6, 1905:

A CONTRIBUTUION TO THE ETIOLOGY OF MALARIA, AND TO THE ANALYSIS OF SOME RELATIONS OF METEOROLOGY TO CHEMICAL PATHOLOGY.

BY HOMER WAKEFIELD, M.D.,
NEW YORK.

IN the syndrome so long identified under the name of malaria, plasmodium and ring bodies have been recently recognized as specific features of blood changes. Lately, all cases presenting the typical symptoms, but not the said blood changes, have been by many excluded as non-malarious. The mosquito, and later the anopheles, specifically, has been identified as an agent of transmission and infection, and now we are face to face with an attempt to impose a recognition of the mosquito, and of the anopheles, as the specific and sole agent of infection.

The purpose of this paper is a protest against these undue excesses of speculative conclusion, which, like all fads, are the consequence of an unwarranted drift of opinion, and are unworthy of a scientific profession. The following fragmentary collation on malaria is humbly submitted as a nucleus of evidence in behalf of my contention that malaria is a syndrome, more typical in symptomatology than in the incidental blood change, or in a specific mode of infection. Moreover that it is essentially a disease of general stasis of catabolism, involving primarily blood destruction, and is, in different cases, caused by the suboxidation of humidity, vitiated atmospheres, etc., by toxicity, of many mosquito bites, by intravascular bacterial toxins, and undoubtedly, also, by direct inhalation of atmospheres heavily impregnated with decaying organic matter, which is absorbed by the blood circulating through the pulmonary alveoli.

The medical writers of the nineteenth century have recognized certain preexisting conditions in certain persons, by virtue of which they were said to possess a proclivity toward the manifestations of certain symptoms or a group of symptoms, which have always been known by the name of malaria. These symptoms briefly were: Frontal headache, pain in the back and legs, occasional chilly sensations, capriciousness or absence of appetite, coated tongue, constipation or diarrhœa, disturbed sleep, foul breath, nausea, enlarged and tender spleen, scanty and highly colored urine, a pallid and sometimes an icteric complexion, lassitude, debility and fever.

It is observed that a syndrome embodying many of the above symptoms, common to humid weather of "open winters," is generally conceived as "grippy," and as influenza when combined with catarrhal affections of the respiratory tract. *Plasmodia malariæ* have been found in the blood, when examined, in some of these cases, but that has only led to diagnoses of malaria, or to la grippe, complicated by latent malaria, and so reported. These syndromes appear to simulate the recognized malaria of humid and rainy weather of spring and autumn of temperate zones, more than that of the summer weather of the same or of a tropical zone.

In the words of Sternberg:[35] "The most marked characteristic of the fevers recognized everywhere as malaria, is indicated by their name, intermittent. But it must be remembered that intermittence is not peculiar to malarial fevers." All of the factors of subcatabolism, hereinafter to be analyzed, figure conspicuously as predisposing and exciting causes of malaria, but the principal recognized cause of malaria, an essential factor, cooperating with the abovementioned factors, is the exposure of the victim to the gaseous emanations of stagnant swamps and marshes, in relation to which the infection transmitted by the anopheles mosquito has been more recently added. A characteristic of typical "miasmatic" atmospheres is its humidity or moisture, and perhaps of no less importance is the presence in the soil of organic matter. Sternberg[35] says: "The general rule holds good that soils rich in organic matter are most prolific of malaria. Such soils are found in low marshy places, in the deltas of great rivers, in the broad alluvial plains bordering great rivers, and in the valleys of smaller streams." * * * An impervious subsoil, of whatever character, is everywhere recognized as a condition favorable for the production of malaria, and this presumably because it retains water, which, as we shall see, is an essential factor." * * * Denudation of soil covered by forest or rank vegetation is, where other conditions are favorable, a very common cause of increased prevalence of malarial diseases." * * * Denudation of the soil probably operates to produce malaria, not only by exposing the surface to the direct action of the sun's rays, and of the atmosphere, but also by setting free effluvia resulting from organic decomposition, which previously were consumed by the growing vegetation." * * * In a general way the importance of heat as a factor in the production of malaria is shown by the fact that malarial fevers are extremely common and virulent in tropical regions; that in temperate regions they are less frequent and less fatal; that they are of rare occurrence during the winter months, and that as we approach the frigid zone they become less frequent and finally disappear." * * * When there is an abundance of moisture in or upon the surface of the soil the atmosphere is humid and mists are of common occurrence. To what extent this atmospheric moisture is necessary or accessory to the production or preservation of malaria it is difficult to say, as soil moisture and atmospheric humidity are so intimately connected in malarious localities that the latter condition cannot well be considered alone."

Thus it is observed that the two essential elements of the morbid miasmata are humidity and effluvia from moist earth impregnated with decaying or other organic matter.

These factors I will undertake to prove are alone sufficient to produce all of the manifestations of malaria, which I hold are those of subcatabolism. Firstly, let us refer to the researches of Oliver[23] for an analysis of the pathology of atmospheric humidity. Oliver's experiments in studying the remarkable effect of altitude in raising the proportions of the red corpuscles and hæmoglobin, were performed by proving that the hæmoglobin index and the red cell ratio are increased by virtue of increased loss of water from the blood, through the skin and respiratory tract, in consequence of the great diminution of humidity of the atmosphere of high altitudes. Now if this factor is so potent in concentrating the serum and in thus raising the percentage of the corpuscles; in the language of Oliver:[23] "It is but reasonable to suppose that the increased consumption of water should counteract this influence of dry air on the blood; and at Davos I found that an extra supply of water reduced the concentration of the corpuscles 3.5 per cent. Furthermore, at Arosa in support of this view, I obtained some evidence which tended to show that in a general way variations in the relative humidity had some effect on the proportions of the corpuscles."

While Dr. Oliver did not carry his researches to the extreme degrees of humidity common to some marsh lands, it is evident that the same ratio of reduction of hæmoglobin would be maintained inversely with the increase of humidity, thus establishing the parallelism between humidity and suboxygenation, and hence systematic oxidation and subcatabolism.

It is interesting in connection with the work of Oliver, that Dr. R. Cadwallader,[2] of California, apparently not cognizant of Oliver's findings, has from extensive clinical observation convinced himself that there exists in malaria a state of hydræmia, which is an essential element of the disease. He also holds that the condition of hydræmia predisposes to infection, which likewise conforms to my interpretation of it as a condition of anoxæmia and subcatabolism.*

Cadwallader sustains his contention with many extremely pertinent and significant facts, among which may be mentioned: In each case observed, there was a history of increased amount of water ingested or of a lessened excretion. Cases of malaria exactly follow, in inverse ratio, the water excretion of the people. In relation to cutaneous excretion he mentions that men, while actively engaged in work involving free perspiration, are never attacked, however exposed, but always succumb after cooler weather and discontinuance of sweat-producing labor. In relation to the kidney function, he mentions that anuria is a serious complication and that diuretics always accentuate the value of quinine, and even succeed in cases where quinine fails, or is not tolerated. In relation to the bowels, he refers to the fact that notwithstanding that malaria so universally attacks the weak and exhausted, those suffering from debility following typhoid fever seem to be largely exempt, probably owing to the associated diarrhœas.

In this connection I quote a paragraph setting forth his argument that other factors than the mosquito bite must be accepted: "If all were equally susceptible, every bite of an infected mosquito would be followed by the disease. Allowing a large personal factor, we would start in the spring with one infected mosquito who poisons two men. A second crop is hatched, and from these two, four cases arise, and so on to the *n*th power and we have an arithmetical progression until cool weather kills the bulk of the mosquitos and the cases recover. But the reverse is true. We see a few cases early in the spring, usually in those sick in the fall. There are rallies and declines until autumn. During all the hot weather when mosquitos swarm and breed rapidly but few cases occur. When cold nights set in the mosquitos breed slowly and are sluggish coincident with a lowering of water elimination, when—*mirabile dictu*—behold half of our season's malaria."

Dr. Cadwallader[2] quotes from Hirt's Obstetrics to account for the postpartum or puerperal malaria: "The whole volume of the latter (blood) is increased, but not by an equal increase of all the constituent parts. The corpuscles are relatively decreased in proportion to the liquor sanguinis. The watery element of the blood is proportionately increased, making the condition of the blood during pregnancy one of hydræmia." * * * "At the end of two weeks it is much nearer a normal condition than it was in the latter half of pregnancy, although it is still somewhat deficient in red blood corpuscles and hæmoglobin."

The above assertion of Hirt is confirmed by the recent researches of Lobenstine,[17] who found: "There is a marked diminution in the molecular concentration of the blood in pregnancy, the average being 51. There is likewise a diminution of the concentration of the blood in the puerperium, the average being 53, but a rise over that of pregnancy." Thus is observed an initial condition in the right direction, only requiring a contributory or co-operating factor to constitute a well defined syndrome of malaria. This brings us to the question, What is the most distinguishing feature of malaria? Manson (Tropical Diseases) declares that periodicity is the only sure sign, and this is denied by Sternberg.[34] Osler[24] says: "If the practitioner will take to heart the lesson that an intermittent fever which resists quinine is not malarial, he will avoid many errors of diagnosis." This again is denied by Moore, Cadwallader, and many others.

A patient exhibiting the syndrome of malaria, may or may not respond to quinine. One will respond to quinine, but fail to show the plasmodium in the blood, another will be negative in regard to the etiological relation of the mosquito. Still another will be lacking in periodicity, etc. I trust that the herewith submitted facts will suffice to warrant the deduction that the real typical pathological condition of malaria is hydræmia, that the symptoms pathognomonic of the disease are those characteristic of the general suboxidation and subcatabolism incident to the hydræmia, and that the attendant blood changes are simply those of the anoxæmia, and are typical of other equally pronounced conditions in general, as for example anæmias.

We have seen that postpartum malaria is undoubtedly a condition of hydræmia, intimately related to subcatabolism, but not specifically as a predisposing agent, to infection. Postpartum and postoperative malarias may be considered as accentuated latent malarias, but they must also be recognized as primary as well as secondary hydræmias *per se*.

It would be just as illogical to ignore postoperative pneumonia, as postoperative malaria; one is just as distinctively a disease as the other. The same etiological elements are largely involved in both, namely, operative or surgical shock and profound

* While possibly Dr. Cadwallader set forth the deduction that malaria is a disease of hydræmia, in ignorance of prior claims of others, it should be mentioned here that Dr. Osler has recognized it many years prior to Cadwallader's writings, with which I am familiar. Dr. Cadwallader's recorded observations are, however, no less valuable as confirmatory evidence and a modern revival of this important attribute of the disease. Dr. Osler, however, alludes to hydræmia only in relation to pernicious malaria. He wrote "The blood is hydræmic and the serum may even be tinged with hæmoglobin."

general suboxidation from prolonged anæsthesia. In postoperative pneumonia, pulmonary irritation by the anæsthetic, and congestion as a result of the venous stasis involved in the shock, similar to that occurring in heart disease, have variously been alluded to by writers as determining factors, while malaria from the same cause appears to be a more or less general subcatabolic disease, minus the pulmonary features, signalizing pneumonia. Neither is necessarily primarily or essentially an infectious disease. Seibert[32] in his statistics of three years, observed that a rise of the relative humidity of the atmosphere during "descending or existing low temperature was attended by an increased number of cases of pneumonia." Thus others than postoperative pneumonias are related etiologically with recognized causes of malaria. Humidity will be recognized as a causative factor of hydræmia, by virtue of its retardation of cutaneous excretion, and of anoxæmia directly, owing to the atmospheric dilution by watery vapor.

Infections are frequently enough found, but no particular or specific organism is pathognomonic, for in divers pneumonias, different organisms predominate, both in virulence and numbers.* In malaria we must admit from accredited facts that both the infection and the plasmodium are more consequential than causative. A discussion on the biological nature will be found later on.

The beneficial effects obtained in malaria by a sojourn in the mountains or other high altitudes, as recently discussed by Holmes,[10] is made clear by the fact determined by Oliver,[23] that altitude has "a remarkable effect in raising the proportions of the corpuscles and hæmoglobin." The temporary ill effect observed by Holmes,[10] on the initial accession to elevations is explained as an accentuation of the effects of the anoxæmia incident to the hydræmia, prior to the attainment of the heightened specific gravity necessary to comfortable oxygenation at the higher altitude. This experience is commonly observed in connection with that part of the Schott treatment of chronic heart disease, in which, if during the mountain sojourn following the first course at Nauheim, altitude is attained too rapidly, ill effects are experienced not far removed from mountain sickness.

The etiological relation of fatigue in malaria is also illuminated by Oliver,[23] who has determined that muscular activity uses up hæmoglobin, and thus in fatigue, the exhaustion exceeds its new formation, thereby producing a low standard. I have elsewhere pointed out that the acidity and toxicity of fatigue products are destructive to the solid elements of the blood in general. Lloyd Jones[12] has demonstrated the rise of the specific gravity of the blood as a result of free perspiration, thus supporting Cadwallader's theory.

It should be observed that we have evidence that the successful therapeutics afforded by diuretics, diaphoretics, and hydragogue cathartics, not only augments the elimination of toxins and other products of malcatabolism, but reduces the hydræmia and thus provides for better oxygenation so necessary for convalescence and future health. Firstly, those toxic products of metabolism which, like fatigue products, inhibit oxidation by virtue of the tissue reactions to the irritation, and secondly, the hydræmia, by virtue of its dilution of the oxygen-carrying elements of the blood and consequent anoxæmia, are simultaneously removed by these therapeutic agents. The fact should not be neglected, in this connection that during periods of suboxidation from any cause metabolic excretory products occur in excess owing to the accumulation of the additional products of suboxidation.

Now to return to the other element of marsh atmosphere, let us consider the chemical factors. I can do no better to establish the presence of the most prolific sources of suboxygenation than to quote literally from Parkes:[25] "The air of typical marshes contains an excess of carbondioxide, which amounts, perhaps to 6 or 8 or more per 1,000 volumes. Watery vapor is usually in large quantity. Hydrogen sulphide is present, if the water of the marsh contains sulphates, which in presence of organic matter are converted into sulphides, from which $S H_2$ is derived by the action of vegetable acids. Marsh gas is also present, and occasionally free hydrogen and ammonia, and it is said, hydrogen phosphide. (Foder, die Luft, p. 84, 1881.) Organic matter also exists in considerable quantity. It was discovered by Vanquel in (1810-11, in the air collected over the Lanquedoc marches), by De Lisle, and again by Moscati (1818 in the air of a Lombardy rice field), and examined more recently by Boussingault (1829, 1839), Gigot (1859), and Becchi (1861). It blackens sulphuric acid when the air is drawn through it; gives a reddish color to nitrate of silver, has a flocculent appearance and sometimes a peculiar marshy smell, and heated with soda-lime affords evidence of ammonia."

We have seen the pernicious effects of a combination of toxic factors of malaria. Carbon dioxide alone, when present in excess in the atmosphere, is capable of producing headache and vertigo, great feebleness of the circulation, and usually slowness of the heart's action, quickening of the respirations, and even dyspnœa of extreme degree. When, however, the air is rendered impure by respiration we have the added effect of humidity and organic matter. Of this Parkes has written:[5] "The effect of the fetid air containing organic matter, excess of water and CO_2, produced by respiration, is very marked upon many people; heaviness, headache, inertness, and in some cases nausea, are produced. From experiments on animals in which the carbon dioxide and watery vapor are produced, and organic matter alone left, Gavarret and Hammond have found that the organic matter is highly poisonous. * * * When the air is still more impure than this, it is rapidly fatal as in the cases of the Black Hole of Calcutta," the prison which proved fatal to 260 out of 300 prisoners. (This instance, however, included the added effect of oxygen famine, *per se.*)

Parkes[25] continuing upon the effects of atmospheres vitiated by respiration, wrote: "Persons soon become pale and particularly lose their appetite, and after a time decline in muscular strength and spirits. The aëration and nutrition of the blood seem to be interfered with and the general tone of the system falls below par."

In this connection it is of interest to recall that there is a recognized group of symptoms from the above-mentioned causes, which have been associated with malaria. Of this Sternberg[34] has written: "It is pretty well established that a non-specific continued fever may result from exposure, in overcrowded and illy ventilated apartments, to the

* For the benefit of those who may be surprised at the above statement, it may be briefly stated that both the *Diplococcus pneumoniæ* of Frankel and the *Bacillus pneumoniæ* of Friedlaender are by no means found in all cases of undoubted pneumonia, and conversely these parasites are predominant in other widely diverse processes, which is evidence that they are not pathognomonic of pneumonia syndromes. Moreover cases of mixed infection are of frequent occurrence. The most constant etiological relation is borne by one or other of the factors of subcatabolism, viz., chill, shock, fatigue, intrinsic and extrinsic chemical and mechanical irritants, etc.

noxious emanations given off from healthy human bodies—crowd poison—and from decomposing animal matters in cesspools, sewers, etc., the idiomalaria of Dr. Edward Miller. This kind of malaria has been denominated 'civic malaria,' as differentiated from 'paludal malaria.'" Again Sternberg[35] alludes to "crowd poisoning" as the true cause of the ill health of northern latitudes which is not infrequently attributed to malaria. He believes the so-called remittent fevers of northern localities to be of this character. He continues: "The tendency among miners, mountaineers, soldiers, and sailors in cold climates is to huddle together in narrow apartments for the purpose of keeping warm, without regard to ventilation, which is necessarily a secondary consideration. A sanitarian who should see the 'dug-outs' or stockade houses which many of these hardy adventurers occupy perforce in northern latitudes during winter months, would scarcely be at a loss to account for the malaise and the fever of a mild remittent type from which they often suffer."

In 1903,[36] in commenting upon subcatabolism I described a type of what I denominated "noninfection malaria which I had observed so much at my medical clinic at Bellevue Hospital. To recapitulate: "If permitted to invent an appellation there is a form of noninfected malaria which I see much of at my clinic among the New York poor, in a class living in houses in which the sun seldom or never peeps, where dampness, filth and poverty reign, and especially in certain seasons of the year when only moderately cold, but damp and wet weather prevails. Though it resembles the infectious malaria of the swamps and the tropics, it is not entirely identical in manifestation. That suboxidation is caused, in these cases, by carbonic-oxide and carbonic-acid poisoning there can be no doubt. Proximity to damp cellars, damp, mouldy walls, badly lighted and ill ventilated rooms are undeniable prolific causes of a suboxygenation of the contained air, which becomes impregnated with the exhaled carbon dioxide, with the carbonic oxide emanations from the damp walls, dark air-shafts and cellars of these poorer classes of tenements and old houses. Also, leaky gas-mains in the streets and pipes in these superannuated buildings pour their toxic monoxides into the already vitiated air of these living quarters. In such cases the gas proves doubly toxic when combined with the noxious vapors from unsanitary water-closets, open and unvented waste pipes connecting with the sewers, sulphureted hydrogen, ammonium sulphide, together with nitrogen. The symptoms of chills, fever, headache, vertigo, nausea, weakness, and rarely loss of consciousness are among the observed results. Another affection, on the order of the types mentioned and often associated, is a form of 'biliousness,' a manifestation of an excess of tissue débris in the system which may be cleared away largely by cathartics, diuretics, and oxidants. In this affection the tongue is loaded with a dirty-looking coating of epithelium detritus, the muddy appearance of the skin approaches nearer to a cachexia than a jaundice (no yellow in the conjunctiva). This condition is usually entirely independent of biliary obstruction, and such an association may not be developed."

Evidence is abundant to prove that practically the same etiological factors and symptomatology are involved in the several malarial types, but we must proceed with the analysis of the other factors as hydrogen sulphide, ammonium sulphide,* etc., which are also the toxic factors of sewer gas and to which Parkes[26] thus portrays suboxygenation sequences: "Cases of asphyxia from hydrogen sulphide, ammonium sulphide, carbon dioxide, and nitrogen (or possibly rapid poisoning from organic vapors) occasionally occur both in sewers and from the opening of old cesspools. In a case at Clapham, the clearing out of an old privy produced in twenty-three children violent vomiting and purging, headache, and great prostration and convulsive twitching of the muscles. Two died in twenty-four hours. These are instances of mephitic poisoning in an intense degree; but when men have breathed the air of a newly opened drain in much smaller amounts, marked effects are sometimes produced; languor and loss of appetite are followed by vomiting, diarrhœa, colic, and prostration. * * * When the air of sewers penetrates into houses, and especially into bedrooms, it certainly causes a greatly impaired state of health, especially in children. They lose appetite, become pale and languid, and suffer from diarrhœa; older persons suffer from headaches, malaise, and fever; there is often some degree of anæmia, and it is clear that the process of aëration of the blood is not perfectly carried on. In some cases decided febrile attacks lasting three or four days and attended with great headache and anorexia have been known. Houses into which there has been a continued escape of sewer gas have been so notoriously unhealthful that no persons would live in them, and this has not been only from the prevalence of fever, but from other diseases."

Thus we observe that the combined factors of "paludal" malaria are sufficient to account for all of the symptoms manifested, without the interaction of microorganisms, though our evidence does not disprove that there may exist a form of the disease due to and typical of the effects of a certain microorganism, which may be responsible for some of the vicious cycles of the progressive processes. I have pointed out in a previous paper[38b] that parasitic organisms always act by producing subcatabolism, and conversely subcatabolic tissue changes, especially gelatinification, predispose to infection.

That Bence Jones,[11] that pioneer among English physiological chemists, believed in the suboxidation basis of malaria, as well as the infectious phase of it, is attested by his remarkable etiological theory, in which, though he singularly has ignored the suboxygenative action of the miasmatic effluvia, in certain writings,[11a&b] in which he directed attention to the fluorescence of quinine, he suggested the probability that as such it acted as an oxidation promoter in malaria.* In a later work he,[11c] referring to what he called the "ague ferment," wrote: "Probably it acts most strongly on the nerves that regulate oxidation, causing for a time contraction of the arterial vessels and consequent suboxidation everywhere. The increased obstruction of the small arteries reacts on the tension of the blood, and this produces increased contraction of the heart, which continues to increase until the obstruction yields, and a state of peroxidation is set up by which the poison is partially destroyed. * * * This theory of ague admits of a reasonable explanation of the action of quinine and arsenic in stopping the paroxysms of the complaint. On the ague poison itself quinine and arsenic may have no action, but they pass into

* Bence Jones analyzes its action thus: "Sulphuretted hydrogen H_2S is decomposed by the ozone of the blood, the sulphur being precipitated whilst the hydrogen reduces the blood to a lower state of oxygenation. An excess of sulphuretted oxygen destroys the hæmoglobin of the blood and thus gives rise to a deficiency of oxygen in circulation."

*Von Tappeiner and Jodibauer[37] have recently reported interesting researches on the fluorescent substances and their dynamic actions, confirming their powers of acceleration of the oxidative effects of light. Edelefson[7] has also added to our evidence as to the oxidating action of fluorescent substances. He has determined that the peculiar germicidal action of fluorescing substance is solely due to oxidation.

every texture from the blood, and combining with the nervous substance on which the ague poison acts, they form a compound on which the ague poison is incapable of producing an effect before it is oxidized and destroyed."

Dr. A. F. A. King,[13] of Washington, D. C., who was the original promulgator of the theory of the transmission of the germs of intermittent fever by mosquitos, has in the last few years negatively supported the hypothesis of the suboxidation nature of malaria* by endorsing the views of Bence Jones, personally proposing and defending the theory that the relative immunity of the negro is due to the opacity of the dark skin to any but the actinic elements of the solar rays, thus protecting him from the red (heat) rays.*

Recent researches by Cabot[1] have divulged the fact that the ring bodies found in the blood in malaria are not pathognomonic of malaria, but rather of the coexisting anæmia, he having found these bodies in many undoubted cases of nonmalarious anæmia and leukamia.

In the foregoing paragraphs upon malaria but little effort has been made other than the submission of evidence without argument in support of my contention that malaria is essentially a subcatabolic disease, and I have given but passing notice to the facts relating to infection, thus resting on my own conviction that it is but a single factor in the etiology. This involves the conclusion that the typical features of malaria are simply expressions of a phase of subcatabolism, and are not peculiar to any particular etiological factor.

The subject of water-laden atmospheres and their relation to disease has been further elucidated by the investigations of Baldwin Latham,[15] in India, on the climatic etiology of the plague. By means of a series of observations of comparative temperatures and degrees of moisture of the atmosphere and the earth, he found that, during periods of great heat and general atmospheric dryness, damp and heavy earthy effluvia are emitted from the ground, and prior to the diffusibility of the gases, they become essentially a factor of subcatabolic disease. There is a generally prevalent idea that humid and damp atmospheres are superior conductors not only of heat and cold, but also of organic emanations of the earth's surface, superficial and subsoil. It is a common observation that during humid and damp weather all bad odors are accentuated, and often odors, not at other times perceptible, are at such times pronounced. In the words of Sternberg: "There are facts which seem to show that an extremely dry air either neutralizes the malarious poison or has no carrying power."

In relation to the plague, Latham[15] wrote: "While it is admitted that plague is due to a specific microbe, it cannot spread except under certain meteorological conditions associated with the conditions of the ground, which must be in such a state as to exhale what is necessary for the propagation and spread of this particular disease. * * * Some authorities are of the opinion that it is greatly augmented by a cadaverous poison in the soil, due to the presence of dead bodies and to refuse from slaughterhouses."

Hodges,[9] in directing attention to an "affinity" between plague and scurvy, wrote: "The affinity between a pestilence and a scurvy is not a slight and supposititious conjecture."

The significance of this will appear later on. Latham[15] wrote: "It will also be noticed that the deaths from the plague, remittent fever, and diseases of the respiratory system other than phthisis, and phthisis itself, follow each other in parallel lines."

Lynch[18] has written of the plague at Pakhoi in 1879: "The disease first makes its appearance in the month of May and continues until September. It is *always* preceded by a similar epidemic among the lower animals, and the general opinion of the Chinese is that it is due to some heavy earthy effluvium, which attacks animals inversely as their respiratory organs are elevated from the ground."

Deane[5] has written of the plague at Pakhoi: "The Chinese are of the opinion that the bubonic plague emanates from the ground, and is favored by a long continuance of dry weather, when the earth becomes porous and numerous fissures appear on the surface, facilitating the escape of whatever causes the disease."

Père Fenouil, missionary to Yünnan, wrote (Parliamentary paper on Plague, 1879): "The plague is really a pestilential emanation, slowly rising in an equable stratum from the ground, and as it increases in depth all animals are, as it were, drowned in its poisonous flood."

Latham[15] wrote: "The conditions which are conducive to the spread of plague are identical with those which give rise to the escape of malaria from the ground. * * * There cannot be a doubt that the conditions which ordinarily produce evaporation from water or land surfaces are identical with the conditions which produce exhalations from the ground, and that these exhalations consist largely of vapor of water, carrying matters injurious to health with them. * * * The general result showed that these earth cylinders* in the daytime, when the air was warmer than the earth, increased in weight, but at night-time, when the temperature of the air fell below that of the earth, the cylinders lost weight; showing that when the air was warmer than the earth, condensation took place, but that when the earth was warmer than the air evaporation took place. These experiments threw considerable light upon the influence of malaria, and explained some well established facts known in

*The points submitted by Dr. King deserve more extended notice than the present paper will permit; yet they may be briefly epitomized as follows: Intermittent fever is spontaneously curable without medicine. Protection from light seems to be the only constant factor by which the spontaneous recoveries become explicable. Esculine and Fraxine comparable with quinine as antiperiodies, also possess fluorescent properties. Crescent bodies are seldom found in the peripheral circulation, where fluorescence is most active. Dr. King specifies heat as an important factor, which is confirmed by the researches of Latham. Dr. King's expressed idea is that the *plasmodia malariæ* are sickly famine stricken parasites. This agrees with my observation that they are degeneration products. Dr. King observes that iodine, which is an efficient remedy of malaria, by virtue of its possible change into blue iodine of starch, simulates the action of the Prussion and Methylene blues, which he does not attempt to explain. The phosphorescent and oxidizing action of *phosphorus* is well known to be due to its allotropic change from yellow to the red form, and the same effect of *iodine*, is its action in producing the allotropic change in contiguous phosphorus, at from 40 to 50 degrees F. lower than the normal temperature, and it likewise promotes the oxidizing activity of nucleins and lecethin. Heat, by decreasing the atomic and molecular weight of tissue constituents, has an opposite effect.

* Dr. King refers to Rhodes and Pepper as having "demonstrated over thirty years ago, long before we knew anything of the malarial parasite or mosquito, that in malarial diseases the fluorescence of the blood is diminished, and that quinine restores the fluorescence to its normal standard, and *pari passu* with this increase of fluorescence the fever disappears and the patient gets well." To students familiar with the pathology of catabolism, the above reference is extremely important, as recent advances in physics have confirmed animal "phosphorescence," as I prefer to call it, as an oxidation phenomenon.

*An earth hygrometer, consisting of cylinders filled with earth freely suspended in a perforated tube, within the earth, at depths of one foot and two feet below the surface.

reference to the influence of malaria, such as the circumstance that malarious countries can be traversed with impunity in the daytime, but are very fatal at night. The fact is that in all warm and malarious countries, especially in the day-time, when the air is warmer than the ground, no exhalations take place from the ground, but at nightfall, when the ground is often very much warmer than the air, these exhalations, accompanied with the vapor of water, escape from the ground. * * * The greatest amount of evaporation or exhalation would therefore take place when we have the maximum temperature of the ground and the minimum dew point; and at all times the exhalation takes place in proportion to the tensional difference between the ground temperature and the temperature of the dew point. * * * It is quite clear that if the temperature of the air increases beyond the temperature of the ground, so that its dew-point is above the temperature of the ground, instead of evaporation taking place, condensation takes place, and to this increased high temperature may be entirely due the sudden stoppage of plague after a certain temperature has been reached, which by raising the temperature of the dew-point, stops all exhalation from the ground and will cause condensation to take place, instead of evaporation. (If the air of a house infected with plague was warmed and saturated with the vapor of water so as to equal or exceed the vapor tension due to the temperature of the ground, it would effectually prevent emanations from the ground, thus imitating the mode nature adopts in stopping such emanations.) So also, where it has been observed that a sudden fall of temperature causes plague to arise, a fall of temperature means that the temperature of the dew-point must fall, and the tensional difference between a low dew-point and a high ground temperature would at once lead to exhalations escaping in large quantity from the ground, and so lead to the liberation of the plague bacillus from the ground, accompanied with the exhalations necessary for its development. Some years ago I made an inspection of the city of Bombay, and found that there had been a general increase of the deaths arising from diseases of the respiratory system other than phthisis, which I found was traceable to the blocking of the natural drainage outlets from the city, and the consequent stagnation in the movement of the underground waters. As these diseases follow in parallel lines the outbreak of plague, it would naturally follow plague was affected by similar conditions. * * * The conditions producing disease in India are in entire accord with the experience in other places, as it has been stated that in Dutch Brabant the people are more or less subject to intermitting fevers, in proportion to the distance of this water from the surface, so that, by looking into their wells, one may form a judgment of the comparative healthfulness of the several villages. (The latter quotation Latham made from Pringle.[29]) * * * It should also be borne in mind that the conditions which lead to emanations from the ground also control the emanations from the human body, and that these emanations are looked upon as extremely infectious. * * * With the dry atmosphere such as occurs in times when plague is most rife, the power to exhale vapors from the human body is enormously increased." Now a quotation from Sydenham on epidemic diseases in general: "There are different conditions in different years. They originate neither in their heat nor in their cold, their wet or their drought, but they depend upon certain hidden and inexplicable changes within the bowels of the earth. By effluvia from these the atmosphere becomes contaminated, and the bodies of men are predisposed and determined, as the case may be, to this or that complaint."

So much for a recitation of fact in connection with water-borne diseases. I wish now to direct attention to the following facts: Firstly, the *primary* cause of malaria and plague is atmospheric humidity or dampness, which may emanate from the ground as well as from rainfall. The humidity of inhaled air, by the production of hydræmia, causes a retardation of oxygenation, of oxidation, and hence of catabolism. The so-caused sub-catabolism furnishes the necessary susceptibility to infection, namely, the gelatiniform decadence of tissue, to which the organic effluvia, according to Latham, the water vapor, are capable of bearing the pathogenic organisms. Secondly, the *secondary* cause of malaria, plague, leprosy, and other (so-called) infectious diseases, is one or another variety of specific microorganism, which is more or less responsible for the vicious cycles of the several diseases and for the typical characters determining the differentiation one from another. Thirdly, even the most typical features of this class of disease do not differ so greatly but that all of the pathogenic anatomical changes are within the limits of the subcatabolic group, as observed in such diseases of nonparasitic origin. Fourthly, the progress of these diseases, both in individual cases and epidemics, is dependent upon the primary causes of subcatabolism, beginning and ending with the essential conditions of subcatabolic etiology. The only exception to this rule are death during the height of the disease and the progressive degeneration, the pernicious cycle of subcatabolism *per se,* which outlives the specific organism, as for example that which attends the evolution and decadence of leprosy, and the transition of tubercle and other lesions into malignant neoplasms. Fifthly, other causes of subcatabolism as chill, fatigue, narcotic habits, sexual excesses, anæmia—in general *suboxygenation, suboxidation,* and *malacidity* may and do act in the capacity of both primary and adjunct or aggravating etiological factors of all of these subcatabolic-infectious diseases. Sixthly, other diseases of the subcatabolic group may be the outcome of one or more of the primary etiological factors of the above-named class of diseases. So often has rheumatism been observed to follow the cause and common manifestations of malaria, that all books on the subject of rheumatism give a prominent place to the malarial theory of its etiology. Moreover in localities where malaria, plague, or leprosy prevails, an individual with any form of subcatabolism is recognized to possess a predisposition towards the particular disease prevalent. Any one can substantiate this from the literature of these diseases (see also Sydenham).

I have pointed out in previous monographs[38] that there are several etiological factors of subcatabolism, which I have not in the present paper connected with malaria, yet it may be said that any causative factor of catabolic stasis may play a part as a contributing factor of malaria, but malaria being a particular phase of catabolic retardation, it must be recognized that its peculiarity of syndrome is largely due to the variations dependent upon the nature of the particular etiological factors involved. Thus we observe that malaria *per se* varies accordingly as it is due to different causes, at different seasons of the year, different localities. It is varied by complications, by management, and by medicinal treatment. The hemorrhagic form of the disease is a good example of this fact. The scurvy of plague has its analogy in the hemorrhagic form of malaria.

There are many who, while viewing the above with favor, will demand more evidence, that the re-

cent conversion of the profession to the monopoly of the mosquito (anopheles) of malarial etiology, is not all that has been claimed for it. To this end I will herewith submit some quotations from other writers that will be recognized as trustworthy, thus showing that the reaction against that theory is a healthy one: "Chenisse[3a] combats the idea that mosquitos should be regarded as the only basis for the etiology of malaria and yellow fever. First of all, the geographic distribution of the anopheles does not always correspond with the distribution of malaria. The disease has even completely disappeared in localities where the mosquitos still remain numerous. On the other hand, there are regions profoundly infected with malaria, where it is impossible to discover any anopheles. Epidemics of malaria have occurred under the influence of late and abundant rains, without the intervention of mosquitos. German army statistics show that the malarial curve is highest in the early spring, and descends abruptly in July and August, showing an utter lack of concordance with the prevalence of mosquitos. The prevalence of malaria can be more readily explained by meteorologic and telluric conditions. The author claims that the mosquito theory has been transferred to yellow fever by analogy only, since the presence and life history of the 'hæmatozoa,' causing the latter disease, have not yet been demonstrated. The condition presented by patients inoculated by infected mosquitoes is probably the inflammatory bilious fever of the Antilles. Concerning the extermination of yellow fever in Havana, the author says that the disease disappears spontaneously after a course of two to four years, and that the sanitary measures carried out on the soil have not diminished the number of mosquitos. Moreover, the war on mosquitos, carried on in certain other regions, has had no influence on the prevalence of yellow fever there."

Chenisse[3b] continues: "Celli mentions districts in which malaria is rife, anopheles abundant, but newcomers are not infected. Francesco points to districts deeply infected with malaria where no anopheles has been seen. Malaria can be propagated without the intervention of a mosquito of any sort. Epidemics after heavy rains have occurred in Algeria. In Eastern Prussia and Posen malaria is general from the onset of spring when mosquito bites must be rare. During July and August the disease suddenly decreases, although the soldiers are most discomforted then by bites. In Bessarabia, in May, 1901, malaria was twice as great as during the previous year, which was particularly rich in mosquitos. At Tomsk, Siberia, malaria commences when the thermometer registers 10° C below zero, which is hardly favorable to mosquitos. The experimental inoculations in yellow fever are suggestive, but the disease inoculated may be inflammatory bilious fever. We cannot attribute its disappearance in Havana to destruction of mosquitos."

Says the *British Medical Journal* (*Literary Digest*, March 5, 1904): "Dr. Emile Legrain, editor of the *Revue Médicale de l'Afrique du Nord*, and Dr. Alcide Treille, physician to the Civic Hospital of Constantine, and professor of the diseases of hot countries, both retired medical officers of the French army, offer themselves as the subjects of experiment. They will submit to be bitten by mosquitos fed on a patient suffering from quartan ague (the only type of fever on which one can count for an accurate and protracted observation). They undertake to use no preventive treatment beforehand, to take no bark or quinine in any form, and to use no antipyretic therapy. They will, in a word, allow the fever to pursue its course in them uncontrolled (with all the hæmatozoa it may please to develop, as long as it may please, and in any manner it may please). They consider Manson's experiments unscientific and inconclusive, and are anxious that the question may be tested on their persons before a campaign (as useless as it is likely to be costly), is entered upon in Algeria."

Many readers who are familiar with my previous writings on, and application of, the pathology of catabolism,[38] will probably demand tangible evidence of the coexistence of combining etiological factors and their pathogenic sequences, which would necessarily be manifested in different phases and stages of subcatabolic processes, of whatever nature. In view of the well recognized disposition of the new-born toward subcatabolic manifestations, varying from the simplest forms to the hemorrhagic affections, the recent report by Peters,[26] of an infant, born of a mother suffering from malaria during late pregnancy and parturition, showing no sign of the disease on blood examination after birth but developing the disease on the 51st day, without being exposed to mosquitos or a malarial environment, is interesting. In the above relation it is of interest that Radcliffe[30] has pointed out that "the initial rigor of fever, moreover, is coincident with wanting warmth, miserable pulse, sunken countenance, blueness of nails, cutis anserina, and other signs of vascular collapse, and subsultus with the most utter prostration of the powers of the circulation." Then emphasizing the suboxidation nature of the process, and elucidating that fever, a hyperoxidation is the outgrowth of suboxidation in general.

Now we are face to face with the probability, supported by negative evidence, that parasitic organisms do not pass the placenta, while conversly we have conclusive evidence that general suboxidation in the mother fosters suboxidation diseases in the offspring. Smith[34] has reported five cases of inguinal buboes, all complications of malaria and without a suspicion of syphilis or other venereal diseases. McElroy[20] has reported spontaneous gangrene, hæmoglobinuria, and other complications of malaria in Mississippi. Winfield[39] reports 25 cases of herpes zoster and cites others occurring in malaria, and expresses his disbelief in a special organism being the only causative agent. Wolf[40] has written interestingly of clinical observations of the intimate relations of malaria with appendicitis, of malaria simulating appendicitis and coexisting with it; plasmodia were found when blood examinations were made. Mays[19] has written on vertigo, with quite constant headache and backache, in cases with well defined history of intermittent fever, which were most effectively and promptly relieved with quinine.

Lerch[16] has directed attention to interstitial nephritis and peripheral neuritis as outgrowths of malaria. He also reminds his readers that "diabetes, gout, and other cachexias, arteriosclerosis and old age, and the severe anæmias may produce neuralgia or cause neuritis; gastrointestinal disturbances, especially constipation, are a common cause of neuralgia and sometimes neuritis. Cold and excessive work are the direct cause of both, though emotion frequently produces neuralgia when any of the remote causes exist, whereas it cannot cause a neuritis." Students of the pathology of catabolism will observe the significance of the related causes named.

Spiller[41] has reported a case of malaria with symptoms of multiple sclerosis. Plasmodia of the estivoautumnal type were reported found on autopsy in every capillary of the central nervous system, and the symptoms were thought due to thrombosis of the capillaries by the parasites. Moore[21] has also

reported interesting observations on the frequent occurrence of nephritis with malaria. He observes that while it is not likely to occur in the single tertian type, it does in a large percentage of the double tertian, even approximately 80 per cent. "The more chronic the case becomes of any infection, the more likely to produce nephritis." "Malaria of long duration and often repeated attacks produce chronic renal disease." "Estivoautumnal malaria gives the greatest percentage of cases of nephritis, 68.7 per cent."

The remarkable report of Craig[4] of 1,267 cases in which the malarial parasites were demonstrated in the blood, 395, or 25 per cent. of them being unaccompanied by the clinical symptoms of malaria, or were masked by the clinical symptoms of other diseases, should lead us to ask whether the plasmodia are really specific parasites producing a particular syndrome, or whether these bodies are products of subcatabolic diseases in general. Craig[4] continues: "Malarial parasites have been observed in the blood undergoing segmentation, and not accompanied by marked symptoms, and in most cases by no symptoms at all."

Gros[8] reports two brothers, successively treated, both believed to have malaria. The first showed ascarides and the second malarial organisms, on examination. Both recovered on quinine. Powell[28] reports himself almost forced to the conclusion, however heretical, that the anopheles is not the sole transmitter of the malarial parasite. At Fort Hamilton, after a careful research and study, he was unable to find any of the anopheles type to account for many cases of malaria treated at the military hospital. Shoemaker,[33] confirmed previous reports on the rarity of coexisting typhoid fever and malaria, basing his conclusion on a large number of examinations made on returned soldiers of the Spanish war.

It would be impossible here to discuss the merits of the theory that plasmodia malariæ are really degeneration products of pre-existing blood cells, instead of parasitic organisms of foreign origin; yet it may be mentioned that their denomination as protozoa only signalizes them as simple animal cells or naked unicellular organisms, of which the white blood cells are quite typical. Englobation by less dengenerate cells is a property commonly observed of both parasitic organisms and cell detritus. Perhaps the most significant features of the plasmodia is their close relation to phases of cell degeneration: (1) Unpigmented hyaline bodies in the red cells, possessing amæboid movement; (2) pigmented bodies still possessing some amæboid movement, but exhibiting some expansion and increase of size; (3) segmenting bodies; (4) crescentic bodies within blood corpuscles; (5) flagellate bodies arising from the intercellular pigmented forms, ovoid bodies, or altered crescents; (6) free flagella (so called). All observers admit the great destruction of red cells and pigmentation of those leucocytes maintaining their identity. Anæmia increases parallel with the attainment of the state of malarial cachexia and the hemorrhagic forms.

I can suggest no better sources of investigation of the problems of cell inclusions and of the antiparasitic interpretation of them than to refer the reader to the writings of Pianese,[27], Dean,[5] Lack,[14] and others who have recorded such brilliant studies into the parasitology of cancer. Pianese in particular, who explains in an exhaustive manner the origin of bodies which have by others been interpreted as parasitic organisms, held as cell inclusions. He specifies among the various ways that they occur, that they arise variously from degenerations of the protoplasm or nuclei, atypical mitosis, or from phagocytosis. It will be recalled that Neisser,[22] in his theory that coccidia, a subclass of the sporozoa, is a specific parasite of cancer, described as crescentic, as a final transition form. However, Cabot's[1] findings of ring bodies as products of pernicious anæmia, lymphatic anæmia, and the anæmia of lead-poisoning is second to none in importance.

Now I wish to submit a few thoughts to bear upon the present conceptions of bacteria in their biological and pathogenic relations. There are undoubted marked variations in cell life, changes in form, structure, and physical expression, as influenced by changed environment and essential conditions of their existence, with which biologists and bacteriologists are as yet unfamiliar. Such changes have been studied by zoölogists in higher animal organizations, and much has been done by evolutionists in the development of our knowledge of variation, acquired characters, adaptation, acclimatization, etc. As far as our knowledge goes, we have reason to believe that the mutations in unicellular organisms and detached and circulating cells of higher animal life are subject to and experience much more pronounced and profound variations as they come into contact with new environments, conditions, influences, and affinities, than the higher and more established and stable forms of life. Yet owing to the difficulties of investigating microscopical forms of life, they have been so little studied that our knowledge of them is very scant.

There are many diseases about which much controversy is now prevalent, as to whether certain microscopical specks observed are the products of pathological cell changes or are parasitic organisms. Clashes are constantly occurring now between biologists and bacteriologists, over the microscopical findings in malignant neoplasms. Malaria has furnished some food for discussion regarding the true nature of the *plasmodium,* generally regarded as a parasitic organism of the simplest unicellular type, an amœba, variously described by different observers as found in divers conditions in the spherical, ring, and crescentic forms. When spherical they are described as of about one-fourth the size of a red blood cell.

Under certain vicissitudes, variously produced, it is well known that unencapsulated cells, as amœbæ and leucocytes, for example, by stimulation contract, greatly decreasing their circumference, and coincidently exuding a high percentage of fluid inclusion. If this stimulation be persisted in, they become granular, and if in a suitable environment, will become impregnated with an excess of pigments, calcareous deposits, or what not, and finally will disintegrate, fragments in ring and crescentic formations being not infrequently found. If this effect was somehow produced on the blood cells the hydræmia and the typical features of the *Plasmodium malariæ* would theoretically be in evidence. This can be taken for just what it is worth.

Any of the above-mentioned causes of malaria, while not all conducive to the transmission or inoculation of a parasitic organism, are without exception undoubtedly producers of suboxygenation (anoxæmia), and, as can be easily proved experimentally in each instance, would produce exactly the same retrogressive features as are above described. Thus from the standpoint of assigning malaria as a disease of anoxæmia, our working hypothesis accounts for all typical features, while from all other standpoints taken singly and individually, it has been necessary to exclude many incompatabilities, which, though too common a procedure in medicine, would insure its dethronement in the physical sciences. In

the words of Dumas: "Theories are like crutches. To find out their value we must try to walk on them." It is evident that conceptions of a subject that are only partially compatible with it, and to some extent entirely irreconcilable with it, would prove to be poor crutches to depend upon. As may be culled from the above contribution, I predict advancement and radical changes in our conceptions of individual cell life during the next decade. The cooperation of divers recognized factors of malarial etiology, as cold, fatigue, etc., in the rôles of predisposing and exciting causes, and as related to infection, I have analyzed and treated more exhaustively than the present paper would admit of, in an unpublished article* setting forth an attempt at a biological classification of symptomatological manifestations of disease in general, in relation to subcatabolism and to the several causative factors of subcatabolism. This paper is commended to those who desire to extend the present line of investigation. The discussion of hemorrhagic, melanæmic, and cachectic features of malaria also will be elucidated by reference to these manifestations as they occur in the above-mentioned biological series, and are discussed in relation to their etiological factors. The interrelations in symptomatology are so strikingly illustrated in connection with the biological series, by the literature of temperament, diathesis, dyscrasia, etc., that I have been led to discuss the biological series in that connection, and malaria thus bears an important relation.

Accordingly as manifestations of the more advanced stages of the biological series complicate, or dominate over, the malarial type of symptoms, the custom has been to denominate them, for example, in the former instance as rheumatic or hemorrhagic stages of malaria, as the case may be, or in the latter instance of rheumatism, or a purpura of malarial origin. Thus we have the malarial theory of etiology of rheumatism. Persons, from the same etiological factors, have acquired divers diseases, as according to nineteenth century literature, was determined by one's preinherent diathesis—malarial, rheumatic, hemorrhagic, etc. Quite a group of diseases, including tonsillitis, bronchitis, asthma, chorea, endocarditis, etc., are listed by reputable authors, variously as specifically connected with malaria, rheumatism, gout, etc., or as diseases of malarial, rheumatic, or gouty diathesis. They are referred to not infrequently as constituting the malarial, the rheumatic, or the gouty series.

A fixed series of manifestations, arranged as they occur in a definite retrogressive order, which I have denominated the biological series, owing to their exhibition also, by the fundamental forms of life, the interrelation of and the manifestation types of stages of this series explains the states of different diseases, as various symptoms or manifestations predominate in, or dominate a pathological process. The biological character and the succession in definite order and stages of events appear to have been overlooked by investigators, or possibly owing to a deficiency of confirming evidence they have, to the best of my knowledge, failed to report it.

Finally, the term Malaria, which is derived from *mala aria* (malicious air), certainly indicates definitely the original use of the term, and, moreover, that the fundamental conception of the real nature of the disease was more correct than that most current to-day. As I have pointed out above, that the symptologic syndrome of the disease is essentially one of subcatabolism, and is largely due to some form of vitiated air, the newly discovered factors, the *plasmodium* and the mosquito, should be relegated to the subordinate position of contributory factors, instead of adopting the absurd and confusing custom of revising our conceptions of a disease *per se*, whenever a new factor is proved or accepted as bearing an etiologic relation, which, owing to ignorance of underlying etiologic actions, we have been unable to reconcile to our preconceptions of the resulting syndrome. Instead, let us profit by the dictum of Liebig: "Every phenomenon of nature is dependent on more than one cause."

THE USE OF SULPHATE OF COPPER ALONE, AND IN COMBINATION WITH LIME, FOR THE DESTRUCTION OF MOSQUITO LARVÆ, AS A DEODORANT, AND AS A DISINFECTANT.*

BY A. H. DOTY, M.D.,
NEW YORK
HEALTH OFFICER OF THE PORT OF NEW YORK

SULPHATE of copper has occupied an uncertain position in sanitation inasmuch as its value has been differently estimated in various parts of the world. This has been largely due to the absence of satisfactory scientific investigation. It was for the purpose of securing some definite and reliable information regarding this agent that a series of experiments were begun early in this year at the New York Quarantine Station. The investigation covered the following points: (1) The use of copper alone, or in combination with lime, for the destruction of mosquito larvæ; (2) as a deodorant; (3) as a disinfectant.

In the tests employed to ascertain the value of copper for the destruction of mosquito larvæ every effort was made to carry out the work in a practical and thorough manner. Superficial wooden tanks divided into two parts were constructed for this purpose, each part having a capacity of fifty gallons; to these tanks was carefully transferred water containing mosquito larvæ taken from pools in districts where this insect was actively propagated. While both sections of the tank were filled with water containing the larvæ, the experimental work, *i.e.* the addition of copper, or copper and lime was confined to one section only, the other being used simply as a control to ascertain the length of time the larvæ remained alive in the water not treated with the agents above referred to. In some of the experiments decomposed meat or fish, sewer water or some other offensive fluid was added to the original pool water in both sections of the tank. This was done to increase the amount of organic matter present in order to ascertain the action of copper and lime in various solutions and also to learn in what kind of fluids the larvæ thrived best. Three stock solutions were used in the experiments. Number 1, consisted of one pound of copper to ten gallons of water; number 2, one pound of lime to ten gallons of water; number 3, one pound of copper and one pound of lime to ten gallons of water. A gallon of one of the above solutions was added to every fifty gallons of water containing larvæ experimented with. This constituted about twelve grains of sulphate of copper for each gallon of water tested, and an equal amount of lime when this agent was used. It was shown early in the experimental work that, so far as the destruction of the larvæ was concerned, the use of copper alone was less effective than when used in combination with lime. This was also apparent in the tests made with copper to ascertain its value as a deodorant. Numerous experiments were made with weaker and stronger solutions of copper and lime than those already referred to; however, it was proven by these tests that the mixture containing one pound of copper and lime and ten gallons of water offered the best and most constant result.

The larvæ contained in the portion of the tank in which the copper and lime alone or in combination were added very soon became inactive, and by the end of twenty-four to thirty-six hours a large percentage of them were dead. It is important to know that while this change took place in the portion of the tank containing the copper and lime, the larvæ contained in the other portion of the tank remained active and passed into the pupal stage, and subsequently became the winged insects. As already stated, this portion of the tank was used only as a control.

Immediately after the introduction into the tank of the copper or lime, or both, the water became turbid, and a precipitation began, which continued for a number of hours. The result was striking even in tanks where sewer water, or decomposed meat or fish had been added. At the end of eight or ten hours in almost all of the tests, the water became beautifully clear. Chemical examination made at the end of twenty-four hours failed to detect the presence of copper in the clarified water. The precipitation and destruction of larvæ referred to followed the introduction of either copper or lime alone, but it was much more pronounced when they were used in combination. An explanation of the above may be given as follows: When water is added to calcium oxide (unslaked or rock lime), the oxide is converted into calcium hydrate. On the addition of this to a solution of copper sulphate a reaction takes place, which forms copper hydrate and calcium sulphate. The copper hydrate, being insoluble in water, forms a precipitate; the calcium sulphate present, if more than sufficient to saturate the water, will also form a deposit. When copper alone is used, the precipitate is as a rule due to the combination of the copper with the lime as a normal constituent of the water. When lime is added with the copper, the precipitate is necessarily more pronounced. This change involves a chemical and mechanical combination with the organic matter present which is carried down with the precipitate. It is in this manner that the organic matter is removed from the water which practically means the abstraction of the nourishment upon which the larvæ unquestionably live. After the addition of lime and copper to the water, the larvæ dies slowly and some succumb sooner than others. This is essentially

*Read before the American Public Health Association, Havana, January 10, 1905.

what will take place in starvation. As already stated, the precipitation and the destruction of larvæ followed the introduction of either copper or lime alone, but was more pronounced when they were used in combination. As proof that the larvæ were not killed by a toxic effect of the copper, the following tests are presented. Larvæ placed in distilled water, which contained no organic matter, and to which no copper or lime was added, lived but a short time. Furthermore it was shown, in the tests made in the tanks, that if a very large amount of organic matter was added to the water experimented with, so much that the copper and lime could only precipitate a portion of it, the larvæ were not materially affected. It was found that the use of lime, which causes a precipitation equal to that produced by copper, killed the larvæ as quickly as when copper was used. In connection with this part of the subject it may be said that experiments in this direction were made with sulphate of iron and alum alone, and in combination with lime. These agents, however, did not produce the satisfactory results noticed when copper and lime were employed.

A careful study of the experiments just cited leads to the conclusion that the destruction of larvæ in water to which copper or lime, or both, have been added is due to the rapid removal of nourishment rather than from any toxic effect produced by these agents.

In the second series of experiments, *i.e.* to ascertain the value of copper as a deodorant, many tests were made with various forms of offensive matter both fluid and solid, including decomposed meat and fish, sewer water containing fecal matter, etc., etc. The same solutions were used as in the experiments made with mosquito larvæ. The experiments showed that although copper acted as a deodorant it was not so uniformly successful as when used in combination with lime. In water made very offensive by adding organic matter from sewers, or decomposed meat or fish, the valuable deodorizing qualities of copper and lime were very apparent. Less than half an hour after the addition of these agents there was but little or no odor perceptible. This result was as a rule permanent, and only in a few instances was it necessary to make a second application. The deodorizing and clarifying effect of copper and lime on offensive and turbid water is remarkable, and can only be fully appreciated by those who have witnessed the experiment. The effect of the mixture on offensive receptacles and apartments such as pails, barrels, vaults, cesspools, cellars, stables, etc., etc., is pronounced and exceedingly satisfactory. This result also follows the liberal use of the mixture of copper and lime on garbage heaps, etc., where organic matter has been in process of decay for a long time and where the odor is very obnoxious. The use of the mixture in the latter instance may be regarded as a severe test. In some few instances it was found that the decomposed organic matter present was in such large quantities that the amount of copper and lime usually employed for the purpose was not quite sufficient to produce the desired result. In these cases an additional half pound of lime was used, thus making the formula one pound of copper and one and a half pounds of lime to ten gallons of water. As a matter of fact even more copper and lime than this may be used if it is deemed necessary. However, the formula generally used (one pound of copper, one pound of lime and ten gallons of water) was as a rule found to be sufficiently strong to deodorize the offensive matter with which it was brought in contact. It must be remembered that in deodorizing solid masses the mixture is used in full strength, whereas in deodorizing offensive fluids one gallon of the mixture is added to from thirty to fifty gallons of the fluid treated.

The need of a practical and effective deodorant has long been fully appreciated by sanitarians. A true deodorant is one which destroys offensive odors by neutralizing them and not by masking them with a stronger odor. But very few good practical deodorants are at our command. The use of the preparations of lime in powder, although commonly employed, are not satisfactory; neither is any deodorant in the form of powder applicable to general use for the reason that it does not insure an intimate mixture with offensive material. The difficulty in securing good results from the use of deodorants in this form is illustrated in attempts to deodorize masses of garbage, etc., in which instances only a portion of the material can be treated, as the powder cannot be properly applied to all parts of the mass. Bromine has for the past ten or fifteen years been regarded as the best deodorant in use, and justly so; however, the employment of this agent is associated with considerable danger inasmuch as it violently irritates the respiratory tract, so much so that, in making solutions of it for deodorizing, it is necessary to break the bottles containing the bromine under water. On the other hand both copper and lime are practically harmless and their use is attended with no danger; besides, they are comparatively very cheap. Sulphate of copper can be purchased for five cents per pound, and lime for three cents per pound. A ten-gallon solution therefore can be made for eight cents. When we consider that a gallon of this mixture will deodorize and clarify thirty to fifty gallons of offensive and turbid water, or in its full strength deodorize a considerable mass of decomposed solid matter, it will be seen that very little expense is attached to its use. Again, in contrasting bromine with copper and lime, it will be found that in treating decomposed organic matter the effect of the bromine, which is very volatile, is transient, and frequent applications must be made to prevent the recurrence of offensive odors. On the other hand a single application of the mixture of copper and lime is generally sufficient; more than two applications are rarely needed. This factor alone is of great practical importance.

Sulphate of copper has a strong affinity for sulphur, forming with it insoluble sulphides. Therefore the value of this agent as a deodorant is largely due to this fact inasmuch as the offensive odor emanating from decomposed animal and vegetable matter is commonly caused by the formation of sulphur compounds.

In the use of copper and lime it must be borne in mind that when these agents are mixed together a precipitate takes place. This contains the important deodorizing elements, and it is imperative that the mixture should be well stirred when being supplied. Care must be taken in selecting the copper and lime and in preparing the mixture in order to secure a satisfactory result. Fortunately, sulphate of copper, commonly known as "blue vitriol," is so cheap that it does not invite adulteration, but it is sometimes confounded with "copperas" (sulphate of iron). Chemically the lime used in the preparation is called calcium oxide, but is commonly known as "unslaked" or "rock lime." It is purchased either in barrels or in tin cans, the latter being preferable as it better insures protection against the air, although, if properly protected in barrels or large receptacles the result is practically the same. Lime which has been exposed to the air and is known as "air-slaked" lime, is worthless for this purpose. The unslaked

or rock lime used in this mixture must not be confounded with chloride of lime. In preparing the mixture which I have recommended as a deodorant, and which is composed of one pound of copper, one pound of lime and ten gallons of water, it is advisable to first dissolve the copper by placing it in a linen or muslin bag suspended by a string just below the surface of the water. In this way it is dissolved much more rapidly than when the copper is thrown to the bottom of the receptacle and stirred. For example, the copper may be dissolved in six or eight gallons of water, leaving the remainder of the ten gallons to prepare the lime which is done by placing the latter dry in a pail or other receptacle and gradually adding water and stirring until the "steaming" or "slaking" is completed. The lime is then gradually added to the water in which the copper has already been dissolved, the mixture being constantly stirred during this time—a precipitate then takes place. In a well-covered receptacle the mixture may be kept indefinitely as a stock solution.

In the treatment of offensive masses, such as decomposed organic matter, garbage heaps, offensive woodwork, vaults, etc., etc., no complicated apparatus is necessary for the application of this mixture. An ordinary garden sprinkling pot, made of tin, and of a large size, is all that is needed for this purpose. This mechanically distributes the mixture. As the latter is rather thick, it is best to enlarge the small openings in the sprinkler by inserting an awl, or some smooth and round instrument. This allows a freer exit of the mixture. In deodorizing offensive solutions the sprinkling pot is not needed, as the mixture is simply added in the proportion of one gallon to thirty to fifty gallons of the fluid to be treated. The mixture of lime and copper will more or less adhere to the various receptacles. However, if it is desired, it can, after a sufficient exposure, be easily removed by a stream of water. In cellars, etc., the mixture may be applied with a whitewash brush. However, for offensive woodwork the employment of the sprinkling pot is preferable. A severe test for the mixture may be found in stables where the ammoniacal odor is very strong and pungent, particularly where urine-soaked wooden floors exist. The good effect of the mixture in these cases is apparent within an hour after its application. The solution of copper alone or in combination with lime so far as my experiments have shown, has no effect upon or does not discolor white linen or cotton goods soaked in this mixture for six or eight hours. At the end of forty-eight hours some slight greenish discoloration in streaks was noticed. However, this discoloration was quickly removed by warm water and soap. As a matter of fact, to deodorize material of the kind just referred to, it is only necessary to let it remain in the mixture for two or three hours at the most.

Experiments to determine the germicidal value of sulphate of copper are now under way in the laboratory at this station. Thus far I am able to report the following:

In tests made with typhoid bacilli in distilled water, tap water, water from sewers and broth, it was found that in distilled and tap water a solution of 1-10,000 killed in one hour. In distilled water a 1-100,000 solution killed in two hours, while in tap water it required from six to eight hours to produce the same result. In water taken from street sewers, a 1-1,000 solution was required to kill typhoid bacilli in one hour, while in broth it required a 1-300 solution for this purpose. It is of importance to note that in these experiments a greater amount of copper was required, as the organic matter was increased in the fluid. In tests made with the cholera organisms, it was shown that they succumbed in a much higher solution and more promptly; for instance, a 1-10,000 solution in distilled water killed the cholera organism in twenty minutes, while it required one hour to effect the destruction of the typhoid organism. It was also shown that a 1-200,000 solution killed the cholera organism in two hours. I have simply cited the above experiments relative to the germicidal effect of copper to suggest what the possibilities of this agent may be as a disinfectant. This part of the investigation will be exhaustively carried out and the result when completed will be published in detail.

In summing up the value of copper alone and in combination with lime, under the three headings given at the beginning of this article, I can state as the result of my experimental work that in the destruction of mosquito larvæ, and as a deodorant, the use of copper in combination with lime is more effective than when used alone. That this mixture destroys mosquito larvæ by rapidly removing from the water in which they are contained the organic matter or nourishment upon which they depend for life, and that this result is not due to a toxic effect produced by the copper or lime. Therefore the range of usefulness of these agents, either alone or combined, in the destruction of mosquito larvæ is limited. In swamps or bodies of water covering large areas, where fresh water and organic matter are constantly being added, the use of the mixture is hardly practicable, and its value in these instances is not very apparent. However, in collections of stagnant and offensive water, where the mosquito larvæ are frequently found in enormous numbers, the mixture of copper and lime is of great value, inasmuch as it not only destroys larvæ, but deodorizes the offensive fluid. In swamps, etc., where there is usually but little sunlight, and where there is the most active propagation of the mosquito, there is no doubt as to the superiority of petroleum, not only for the destruction of the larvæ but in driving away the winged insects. I desire to be emphatic in the statement that I suggest the use of copper and lime, or petroleum only when it is impossible to carry out the scientific and radical measures for the extermination of the mosquito, *i. e.* proper drainage and the observance of the laws of modern sanitation.

In regard to the use of a mixture of copper and lime as a deodorant, I believe it to be the most valuable and practical agent we possess at present for this purpose. Its action as a deodorant is rapid and permanent, it is practically harmless, cheap and easily made, and seems to comply with the requirements of a typical deodorant. Furthermore, its range of usefulness is extensive, as it can be employed equally well for deodorizing solids or fluids.

As I have already stated, but little can be said at the present time regarding the germicidal value of copper. However, it is likely that the publication of the results of the investigation regarding this agent, which is now being carried on in different laboratories in this country, will furnish valuable information in this direction.

Quarantine, S. I.

Alpine Disasters.—According to the *London Globe* the present year will prove to have been the most unfortunate on record for mountaineering fatalities. In 1898 there were 37 fatal ascents, 47 in 1899, 48 in 1900, 63 in 1901, 119 in 1902, and 148 in 1903. For the present year the total is 152 for the Italo-Swiss side and 150 for the Austrian and French Alps.

THE "SUB-CONSCIOUS SELF."

By J. ALLEN GILBERT, Ph.D., M.D.,
PORTLAND, ORE.

One of the most curious marks of distinction between man and his brute companion is the fact that at times the former shows his inconsistency by demanding proof for his own existence; or, what is equivalent, he realizes that he exists. While some would have us believe that mind has no reality other than as a mere epiphenomenon to the real underlying current of material reality, others again, not satisfied with their own identity, demand that we accept the tenet that each man has two selves. Still others, as if attempting to try our credulity in the elusiveness of human reason, deny the existence of mind as an entity and yet surprise us by telling us they believe in a sub-conscious self. No wonder that in the presence of such juggling with the unity of personality one at times longs inadvertently, even though inconsistently, for some criterion as an absolute proof whether "I be I."

Has Mind Any Reality?—Could mental phenomena be given length, breadth and thickness all controversy would vanish, but, nevertheless, the non-spatial character of consciousness is no excuse for denying it action and reaction, even though those terms do tend to carry with them a purely physical significance. We speak continually and without apology of the effect of mind on body, of suggestive therapeutics, of the motive force or power of an idea, et cetera. Are they mere terms to fill in an inexplicable gap, or are we to give them causal significance? Dare we impose moral obligation on man and yet hold to the universal application of a purely physical law of causation? In an explanation of mind as an interaction of atoms we forget that the essence of interaction is relation and that relation demands a unitary consciousness as a subject. Beauty, relation, harmony and similar terms demand a unitary subject to which they can be referred. To attempt to prove knowledge of self and personal identity would be to attempt to prove that which must be assumed before any truth can be stated. It is one of the axioms of psychology. The ultimate psychic fact is "I know"; or what is equivalent "I am I"; or, still more briefly, "I." For the present discussion, it is unnecessary to state or defend the ontological entity of mind. Even should we dogmatically assert its ontological entity it would only be doing exactly what materialists do who postulate the brain as the only reality to be dealt with in speaking of psychic phenomena. The brain *as an object of experience* is subject to the laws of perception; and perception is through and through a psychological process. The positing of objective realities is by no means a simple process when analyzed according to the laws of perception. However, each man knows his own identity by direct experience, and viewed thus as a psychological fact such knowledge of identity must be looked upon as the ultimate requisite for all thought. We ascribe unity to things but, when analyzed, things are anything but units, the only physical unit being found in the hypothetical atom whose unity is, after all, based upon and derived from the unity of consciousness which every man knows himself to be. Of all things none is so real as one's "self."

What Do We Mean by a Self?—Generally speaking, man considers himself to be that which can be looked upon as his own conscious experience. I am what I am to-day because of the circumstances in which I am thrown. A myriad of agencies are, in a sense, determining my self-content. As an individual my present content of consciousness, whatever its origin, is the climax of a long series of conscious experiences known to me as a continuum which was and now is. It might be somewhat tautologically expressed by the one sweeping statement "all that is not other than me is I." This, however, is equivalent to merely saying "I am I" or "I." Inexplicable? Yes. No one attempts to explain existence in any other way than by existing. Hume, that master-sceptic, acknowledged that even though at his desk he could argue himself out of existence, yet in the daily contact with fellow-men his own reality forced itself upon him with irresistible conviction. All attempts to prove one's own existence or non-existence end in a *reductio ad absurdum.* The unit we call self is indispensable to any statement or argument.

Whatever else this "self" may be it surely is not the physical organism as such. All, it would seem, agree to that, and all alike agree to a very intimate relation between consciousness and the so-called physical organism. In fact, indisputable proof of the dependence of conscious life upon nerve processes is to be found with little trouble, but when you reverse the statement and claim that a brain or nervous mechanism, *as an object of experience,* is equally dependent upon perception, which is a psychological process, then we hear dissent in every direction. One statement is as true as the other. Neither is false nor do they contradict each other. In perception the subject and object are of equal importance and their positions can be reversed without violence to the truth. Every object, of whatever kind, is what it is only in relation to something else, and causal relation is but a deduced law by which to explain events chronologically. It can not be said that any one person is the cause of any other and yet for the time being every individual gets his existence out of the person or thing upon which he has his attention exclusively centered. That which engrosses one literally makes him. When one says "mind what I say," he calls upon his hearer to take what he says and apperceive it, *i.e.* build it up into his own self-consciousness. In that sense the one literally becomes or, you might say, causes the other. Also, vice versa, the object, upon which his attention is centered is in the same sense dependent upon his synthetic perceptive powers for its existence *as an object of experience.* What it is other than that it is folly to ask, for science is based upon experience, and back of experience we can not go. Kant's "Ding an sich" is a worthless abstraction having no counterpart in experience.

This self of ours, then, in which we have such a warm interest, is that which is built up or builds itself up (if the term be preferred) out of the objects or stimuli which fall within its grasp at the time. It is, of course, manifest that this is no explanation of how consciousness came to exist. It is just as futile to ask how consciousness comes to exist as to ask the origin of so-called matter. All reality as an ontological entity merely is. Causality is an afterthought to explain events, and all explanation begins and ends in accepting the unexplained. The continuum or unity of experience which every man knows by direct experience is "self." That it is exceedingly complex in its relations is only too manifest. Stimuli too feeble or foreign to the nature of the physical organism to awaken a conscious counterpart nevertheless have their effect in modifying the substratum which does, so to speak, mount to the realm of full consciousness. All of us have had vague feelings of a change in surrounding conditions without being able to point out definitely the physical changes which have wrought the indefinite

conscious content of the moment. Who has not found himself humming a tune and been subsequently surprised to encounter some one humming the same tune? Entirely unconscious of the fact that his humming was started by having heard the other person, he ascribes the mystery to a peculiar coincidence, not realizing that the impression, now lost entirely from the content of consciousness, was at one time a flash of consciousness of sufficient strength to set in motion that train of experiences which is now recognized in its full significance but without apparent cause or precedent. Because the original impression is lost from memory he classifies the whole as unconscious physical activity. On the contrary he has gathered up the indistinct and incorporated it as part and parcel of his conscious life, even though it has been lost from memory as an individual state of consciousness and has been engulfed in that continuum we call "self." To gather up the sum-total of such subliminal impressions as these and designate it a "sub-conscious self" can only be figurative. Even should they attain unitary reality it would be more nearly the truth to look upon it as a second self rather than as a "sub-conscious self."

Is There Any Distinction Between Consciousness and Self-Consciousness?—The dividing line between the conscious and the unconscious is exceedingly difficult to draw. That all microorganisms are endowed with "wills of their own" is a conception not devoid of truth, for existence itself is evidence of the presence of spontaneous activity. However, there is danger in carrying our own conscious experience over into things which simulate externally what we experience. Too often perceptible motion is held to be the sole criterion of life. Recent investigations would indicate that spontaneous motion is to be found even in crystals. The hair from the horse's tail soaked in water comes to move in a most mysterious way and it takes but little imagination to give it a volitional existence equivalent to that of the angle worm disturbed in its earthy home. Observe the man who is absorbed in some idea which envelops his whole being. Motionless, with eyes staring into space, even the reflex of winking absorbed in the higher nervous mechanism involved in mental exertion, he appears a lifeless statue, and yet here is the highest intensification of conscious existence, though self-consciousness as such is perhaps reduced to a minimum. Who has not lost himself in the harmony of some symphony, in the intricacies of an absorbing plot or in the solution of some problem? Here is the epitome of consciousness and yet self-consciousness only emerges in the recovery of ourself from the stream which is carrying us along. This is the proof of our existence in that we can wrest ourselves from the whirl of events and posit our own existence as a real unitary being capable of being affected as well as taking part in and affecting the course of events about us. To ask how or why we do it is to ask the origin of existence, which is absurd. We must accept existence as an axiom with which to start. The fact that the mind can appear to itself at all is the most valid proof of its own reality. We may add data in an attempt at proof, we may argue this and deny that, but after all we continually return to the point from which we started, viz., our own unitary self-conscious existence, *i.e.* "self." It is a reality, which will not down. To argue its nonentity is the strongest proof of its existence, for argument, relation, thought and kindred activities demand a unitary substratum for their basis. This substratum, whatever its origin, is for each man all he is or has in the world. The conscious pervades all reality, but the self-conscious is the trademark of personality.

What Is the Relation of This "Self" to the Physical Organism?—All physiological and physical explanation is based upon the atomic theory, and if all reality is to be referred to atoms then all that is must in some way be composed of atoms. Consciousness would thus lose its unity and identity in a complex of atoms in which there is no real unity. To presuppose a unit as either the origin of or result of this complexity of atoms is to surrender the original postulate of the atom as the ultimate unit of reality. Grove tells us that particles of water are estimated to be, relatively to their size, as far apart as a hundred men would be if equally distributed over the surface of England; yet, if we are to believe our materialistic brethren, out of the friction of these remotely separated units, arises that unique unit of experience which we designate self or personality. To be consistent, if this personality in turn is granted any sort of reality, it too must be made up of atoms, but this destroys the real unity which we know ourselves to be and also contradicts the original postulate. In consistency with the atomic theory no unit can be reached other than the original atom with which we started. However, if we stop to consider that the atom is but a hypothetical unit based by analogy on the self-conscious unit we know ourselves to be, the inconsistency becomes all the more flagrant. Either the mind must be looked upon as quantitative or the atomic theory does not apply to consciousness as such. If mind is quantitative then in consistency with the atomic theory it must be granted that it is a real entity. If the atomic theory does not apply then there must be sought other grounds of explanation than those based upon causation and the atomic theory when the relation of mind and body is under consideration.

The atomic theory does not apply to consciousness. It is but a method of dealing with physical phenomena, and so long as kept within these bounds it works. Outside of that realm it is utterly inconsistent, contradictory and inapplicable. It is a cosmological and not an ontological theory. Ontologically there is no antithesis between mind and body. Men have ever struggled to understand or explain how molecular changes are transformed into consciousness, whereas from the standpoint of reality there is no transformation at all. You may say, if you choose, that mind is a "result" of the interaction of atoms, but if so, you must grant the "result" some sort of entity, else, in consistency with the hypothesis, it is not a result. To merely state, as Huxley does, that mind is an interaction of atoms, is but to say that mind is an abstraction, for interaction is but an abstraction. In this we find ourselves in another contradiction, viz., unity is necessary to abstraction instead of being the result of an abstraction. It is just as consistent to explain the lightning by the clouds as to explain mind by matter. The one is indispensable to the other so far as our understanding of them both is concerned, but one reality can never be explained by another when both are but the outgrowth of a unitary substratum, the comprehension of which is necessary to an understanding of either. Huxley may say: "Thought is as much a function of matter as motion is," and yet it is unnecessary to point out the contradiction in such a statement, for he himself contradicts it by adding elsewhere: "I am utterly incapable of conceiving the existence of matter if there is no mind in which to picture that existence"—a complete confession to the action and reaction of mind. Each statement is but the result of consideration of the same reality from two standpoints irreconcilable on the grounds of perception as now held. The same double-sided reasoning led Kant into his celebrated antinomies

which were the result of arguing a while from the physical side of reality and then a while from the psychical, with an attempt to harmonize the two when in fact there is no antithesis between the two and ontologically both blend with an intimacy which defies analysis.

Can "Self" Be "Subconscious?" — That which makes me is the fact that I know myself to have been in the past and that I am now. Of what is that continuum made up which asserts its own identity as the content of my present experience? The term "made up" seems to imply a spatial compound and is therefore in a sense objectionable, and yet that stream of conscious experience carried along in memory constitutes the self in which men manifest such varying degrees of pride. That the content of self may and does change from time to time is a matter of every-day observance, and, speaking in a loose popular sense, we have as many selves as we have diversities of interest. The intimate application of mind and body leads us at times to look upon the body as a self, but in their thoughtful moments but few men will assent that they are either their bodies or their clothes. However, as to their mental make-up, but few men are unaffected by them. The girl who delights in donning her mother's clothes or the boy who struts about in his father's boots experiences an expansion of personality which it is difficult to keep from designating as a spatial enlargement of self, though we well know that space is in no sense objective. Every one finds himself enlarging to include, as it were, his personal belongings. On the other hand, how we shrink within ourselves like a snail in his shell when (if you will pardon the slangy but significant expression) "we give ourselves away" in some ridiculous blunder, of which we are ashamed? It belittles us. There is less of us in our own estimation and in the estimation of others. We feel our circle of influence contract and, after all, the magnitude of a man is the extent of his influence. Gradually every man builds up a sort of psychic reserve which he, as well as others, recognize as his "self." Through strife one obtains his existence and through strife the same is maintained. No action or reaction is so insignificant that it is lost sight of in the great maelstrom of reality.

Such distinctions as "above" or "below" the threshold of consciousness seem uncalled for, because whatever comes into consciousness must of necessity be above the threshold for the time being. To speak of a subconscious or unconscious self would be about the same as speaking of black light, dry water, or, as Schopenhauer puts it, "wooden iron." In order to be a self at all one must at least be conscious. That one may sink to a lower or rise to a higher realization of self is a matter of every-day experience, and the voluntary is at times exceedingly difficult to separate from the mere reflex. Changes in one changes the other, but the two are ever separate.

Can a Man Have Two or More Selves?—The answer to this question depends entirely upon what meaning is given to "man." Psychologically man does not have a mind or self, but he *is* mind, and hence the query whether man can have two selves resolves itself into the question whether one can be two. To speak of man psychologically as anything but a unitary being would be to destroy the very principle of identity which serves as the basis of personality.

If by "man" is meant the zoological animal, then facts force upon us the admission that there are cases in which two separate, distinct streams of consciousness are to be found correlated with one body, at least alternately, if not simultaneously. The physiological processes underlying such a condition of affairs is as yet almost entirely unknown, but not more unknown than the physiological processes which underlie the unitary psychological manifestations commonly assigned to every normal individual. Both are unknown, but because one is common we are not so insistent in our demands for an explanation. A division of the cerebrum into hemispheres does not help us out of the difficulty, for there are cases in which at least four distinct personalities are manifested in the same physical organism. Each, no doubt, has its physiological counterpart, if not entirely distinct, at least sufficiently so to allow of distinct, full developed self-consciousness. In the consideration of a "sub-conscious self" we are dealing with a psychological problem, and to designate it as a conscious self reduced to minimum or in any way related to the true self is to beg the question and admit that the true self is other than it is assumed to be. In cases where the so-called subconscious self comes into question it is not at all a case of "sub-conscious" self, for a self *must* be conscious, but it is a second self as truly separate as any two persons manifested in different bodies. Elements of one may be in the other, but *as a self-conscious continuum each is distinct from the other* where two or more personalities manifest themselves. Any group of phenomena which may appear related to a conscious life and yet which does not rise to the dignity of a distinct self must be looked upon as unconscious rather than as "sub"-conscious if by the latter term is implied anything which would indicate the possibility of self being anything but conscious.

I repeat—man psychologically *is* mind, he does not *have* mind. To state that any man or every man *has* two selves either neglects the psychological nature of man or else forces us into the contradiction of stating that every man *is* two selves.

SOME PAINFUL AFFECTIONS OF THE FEET. DIAGNOSIS AND TREATMENT.*

By CHARLES OGILVY, B.A., M.D.,

NEW YORK.

ATTENDING SURGEON, RANDALL'S ISLAND HOSPITALS; ATTENDING ORTHOPEDIC SURGEON NEW YORK POST-GRADUATE HOSPITAL AND TO THE DAISY FIELDS HOSPITAL FOR CRIPPLED CHILDREN, ENGLEWOOD, N. J.

It would be difficult to overestimate the value of the human foot, though I fear we too often forget its importance and neglect its care. Just as soon as the child begins to walk, possessing then what we may call the perfect foot, beautifully correct in outline and anatomical form, just so soon is this foot often enveloped in a tight-footed stocking and oftener in a tightly fitting shoe.

In a growing child the question of most importance in relation to the shoes seems too frequently to be the length of time that they may last, irrespective of the facts that they may have become too small, cramping the foot and so interfering with proper development; that they may have worn down unevenly; that the ankle no longer is supported by the upper, and that the general condition of the shoes may be producing marked deformity of the feet. In adult life, the style of footwear we purchase usually depends upon whatever fashion may then be in vogue. Fortunately, the fashion during the past few years has become somewhat better educated.

This is but one phase of the subject. Think of all the uses and abuses our feet are called upon

*Read before the City Hospital Alumni Society.

to endure. Bearing the weight of the body, which may be between two and three hundred pounds, not only in walking and running alike on rough roads or smooth, up and down stairs many times a day, but also (which is a much greater strain) standing for hours at a time; subject, too, to all degrees of heat and cold, with little consideration of whether wet or dry, and often bathed in excess of perspiration. Little wonder, then, that so many are suffering from such painful affections, as we will here discuss.

When we stop to consider how dependent we are upon the foot—how absolutely essential for our very existence—its proper care and treatment becomes a subject of very serious consideration. Many evils can be averted and many conditions cured.

The Question of Rheumatism.—I wish we could eliminate the diagnosis of "Rheumatism of the Feet," so often made when the patient presents himself to the practitioner, complaining of indefinite pains referred to the foot and ankle, and sometimes radiating up to the muscles of the calf. Patients have come to me with this diagnosis having been made without the shoe even having been removed for the proper examination of the foot.

It was just last week that the case of a young man, 24 years of age, was called to my attention who had been treated by several physicians for rheumatism, so called—had taken a course of bath treatments, and finally had drifted into the hands of an osteopath, who informed him that one of his vertebræ was dislocated, and that this was the cause of all the trouble in his feet. The man had been suffering from flat foot which had become markedly deformed, the arch having completely broken down and the foot everted. Walking is difficult and causes him severe pain. Surely the time has come when such cases should be diagnosed at the earliest possible moment, and our patients protected from running the gauntlet of shoemakers, chiropodists, masseurs, and osteopaths, with such unfavorable results.

The natural foot is broadest across the toes, gradually tapering toward the heel; the outer border is straight, the inner border curved outwards, this outward curve of the internal border being obliterated when the foot is bearing the body weight. The longitudinal arch is composed of the bones of the tarsus and metatarsus, which may be divided into two—the outer formed by the oscalcis, cuboid, fourth and fifth metatarsal bones—the inner, in which there is a much higher arch formed by the astragalus, scaphoid, the two cuneiform, and the first, second, and third metatarsal bones; the arch is distinctly seen when the foot is in repose, but broadening or flattening out under pressure.

When the foot is supporting the body weight the strain should pass along a line drawn through the center of the knee-joint, along the anterior crest of the tibia, through the center of the ankle-joint, and continued forward on the dorsum of the foot and over the second toe. This relation which the foot bears to the leg must always be very carefully noted; any change in this relation means deformity —and such deformity as is most frequently accompanied by pain.

Eversion.—Of these deformities, the most common is the eversion of the foot, pronation, or what is usually termed weak ankle. The foot is everted, the internal maleolus projects very prominently, the toes point outwards, and the line of strain no longer falls through the center of the foot, but to its inner side, throwing excessive weight upon the inner half of the longitudinal arch. And what is the result?

The arch is supported by muscles, ligaments and fascia. Should the superincumbent weight not be very great, these girders are able to withstand the strain. This is often seen in the case of children. But if this deformity is allowed to remain uncorrected, the child grows older; the body weight increases, and the overtaxed foot gradually weakens; muscles no longer exert sufficient power to act as supporters; the ligaments and fascia gradually give away; the astralgus scaphoid and internal cuneiform bones become depressed, pushing in front of them the inner metatarsal bones; the head of the astralgus and the tubercle of the scaphoid appear prominently on the inner side.

The foot having lost its elasticity breaks down, and we have as a result the flat foot.

Flat Foot.—The earlier symptoms are those of a tired, vague feeling of discomfort, without any definitely located pain; at first noticeable only after standing for a long time, and relieved by resting or by walking; then gradually a slight aching is complained of, often relieved by walking on the outer side of the foot. Later follow definite and continued pain and tenderness referred to the sole and radiating up the calf, due to the fascia stretching and the arch beginning to give way. There is also pain on the outer dorsum of the foot, due to the impinging of the external maleolus upon the os calcis. The foot after a time becomes rigidly fixed in this deformed position of hypereversion.

An early diagnosis is of the greatest importance, for it is a very difficult task to transform an everted painful foot with a broken-down arch into one which is capable of performing all its functions without pain or discomfort.

Flat foot in its first stages is not diagnosed correctly in 50 per cent. of the cases. I am speaking now from both clinical experience and private practice work. Usually the diagnosis of rheumatism is made; and although rheumatism and gout are among the predisposing causes, yet these invariably present symptoms elsewhere and should not be confounded with the weakness and deformity of flat foot.

The diagnosis should be made before the muscles, ligaments and fasciæ have stretched sufficiently to allow the arch to break down. Thus we should diagnose the flattening rather than the flat foot; and if we would bear in mind that the everted or pronated foot is a weak foot, and one which bears the strain of the body weight at its weakest point, we should often be saved from errors in diagnosis.

The treatment of flat foot is the treatment of deformity. For simple eversion or pronation, with a well-formed arch, the Thomas heel should be worn. This heel is extended about three-quarters of an inch farther forward than the ordinary heel, and has an elevation on its inner side of from one-eighth to one-half inch, gradually sloping to the outer side, so that the under surface is smooth and even. This not only corrects the deformity of pronation, but also increases the inner longitudinal arch by bringing the ball of the toe to a lower plane. This heel I have used with the most satisfactory results.

When the case is more marked, and the arch needs a firmer support, then a plate should be worn. The plate being one which not only supports the longitudinal arch, but also prevents the foot from spreading laterally. Such we have in the Whitman Plate.[1] This should extend from the center of the heel to just behind the point of pressure of the ball.

The cast of the plate should be made from the impression of the foot in soft plaster of Paris, the patient sitting upon a chair and placing his foot firmly and evenly into the unset plaster. From these molds casts are made, over which casts the

plates are then modeled. Before modeling the plates over these casts the arches should be slightly raised, for plates to give sufficient support must be a little higher than the arch of the flattened foot.

A plate should never be applied to the acutely inflamed foot. By so doing, additional irritation is set up, and the pain and inflammation is increased rather than relieved. Such a condition should have complete rest.

A plaster of Paris bandage usually relieves inflammation within two or three weeks. In but slightly inflamed cases the flat foot pad and adhesive plaster strapping may be used with very beneficial results. The pad is cut to fit comfortably in the arch, carefully beveled on its edges, extending from a point which is anterior to the point of pressure on the heel to a similar point just posterior to the ball of the toe; laterally from the center of the sole to the inner side of the foot, covering the head of the astragalus so as to support the astragaloscaphoid articulation at this point. This pad is held securely in this position by adhesive plaster. Three or four strips of plaster about 1½ to 2 inches in width are applied. This should begin at the outer dorsal surface and be brought inwards across the sole, and then carried spirally up the leg, winding from within outwards; the foot inverted and adducted as much as possible at the same time. Cross strips an inch in width then applied to secure these more firmly, and a bandage over all, completes the dressing. When the inflammation is relieved then the flat-foot plate may be worn.

Another class of cases in which the plates should not be used are those in which there is marked eversion and rigidity; for it can be easily understood that no steel arch could ever be made that would support the foot in this deformed position. This condition has been termed flat foot of the third degree, and demands operative treatment.

The operation is the correction, or rather I should say overcorrection of the deformity to that of varus. This may be accomplished by simple stretching. Tenotomies may be necessary—usually tenotomy of the peronei tendons are sufficient;—in more severe cases the removal of the scaphoid. After operation the foot remains in the overcorrected position, in a plaster dressing for about two or three weeks. Plates should then be made and a light brace running up the inner side of the leg and fastened to the plate should be worn for several months. The patient may be allowed to walk about four weeks after operation.

Exercise and massage should be carried out systematically and conscientiously—in the earlier cases to strengthen, in the more advanced cases to correct deformity and at the same time to enable the foot to retain its correct position. The following are the exercises:

1. Tiptoeing, rising and falling rhythmically with the foot, a little inverted and heels slightly apart.
2. Raising the body, rushing upon the outer edge of the foot.
3. Forcible inversion and adduction.

These should be performed by the patient three to four times a day from five to ten minutes each time.

4. Postoperative manipulation which always should be performed by the surgeon.

Metatarsophalangeal Pain.—This painful affection to which Morton[2] first called attention, is that of an acute pain of sudden onset referred to the region of the four metatarsophalangeal joint. It is sometimes of a burning character and may be accompanied by the sensation of something slipping, or dislocating, and is often described as such by the patient. This pain may be induced by stumbling or by walking upon a pebble or sharp elevation. Sometimes, too, by a sudden wrench of the foot, nor is it always referred to the fourth, but also the third and second metatarsophalangeal joints radiating to the toes and to the dorsum of the foot, the pain is severe. The first and almost irrepressible impulse is to draw off the shoe, and massage and exercise the foot. This relieves the acute symptoms.

The cause of this pain is due to weakness to the anterior arch which may not present any deformity, or show any external sign of inflammation.

The treatment of this condition is the support of the transverse arch with a felt pad and adhesive plaster. The adhesive plaster is drawn snugly around the arch slightly exaggerated by lateral pressure, thus giving additional lateral support. In chronic cases, the shoe should have an elevation on the inside of the sole to support the weakened anterior arch.

Painful Heel.—Less frequently met with is an acute tenderness on the under surface of the heel due to a bursitis. The pain is slight at first, but as inflammation increases, it gradually grows more severe and becomes so tender that the patient walks with an uneasy gait, throwing the weight of the pad as much as possible upon the toes, thus protecting the heel. It generally occurs with flat foot or a weakened longitudinal arch.

Our aim in treatment is to relieve the pressure upon the inflamed bursa, and this may be done by hollowing out the heel under the side of the bursa. When it is accompanied by flat foot, I have extended the flat foot plate backwards over the heel, making a slight depression in this extension. A plate thus made will be worn with comfort in many cases in which a short plate causes considerable pain. Should operation be necessary, it is better to remove the bursa.

Shoes.—The subject of proper footwear is a most important one, in considering the treatment of all painful affections of the feet. But time will not permit to enter on this subject in detail; suffice it for me to emphasize the essential points of a properly fitting shoe, so well enumerated by Sampson.[3] "The angle of lateral deflection of the shoe should be the same as that of the foot in its adducted position. A straight inner edge, or, if hallux valgus exists, an inner edge a little higher than the inner edge of the foot. The front of the shoe of the same depth along the inner edge as the thickness of the foot. At that place the shoe, convex, not concave, along the outer border of the shank at the mediotarsal articulation. The forward part of the shoe should be wide as the thickness of the foot at that place, thus giving room for the individual toes to rest on the sole. The posterior portion of the shoe should grasp the heel of the foot firmly and be well supported. There should be no dorsal flexion of the shoe. The distance from points in the shoe corresponding to the heel and distal end of the first metatarsal bone must be the same as in the foot. The shank of sole must be convex along the outer border and also up higher on the inner side. The sole of the front of the shoe should be flat from side to side. The lower and broader the heel, the better. A little lateral extension of the sole makes our base of support wider. The bottom of the last or the inner sole pattern must include the area covered by the weight-bearing portion of the foot."

AN INFLAMED APPENDIX IN AN INGUINAL HERNIA, SIMULATING STRANGULATION.

By JOSEPH E. GOLDING, M.D.,
BROOKLYN, N. Y.

The case here reported occurred in the service of Dr. J. C. Kennedy at St. Catharine's Hospital, Brooklyn, and was operated on by the writer. It shows the similarity in symptoms presented by an acutely inflamed appendix, occupying a hernial sac, and those of strangulation, and the difficulties in diagnosis of such conditions.

The patient, a Hebrew, age 68 years, was brought to the hospital on July 21, 1904, complaining of pain in the right inguinal and scrotal regions, vomiting and constipation. Examination revealed a firm, tender tumor in the right side of the scrotum, over which the skin was red and glazed, and which, the patient informed me, had been there twenty years. Two days before his admission to the hospital it became painful, and he suffered from vomiting and constipation. On admission the tumor was irreducible, dull on percussion, not translucent nor fluctuating, and gave no impulse on coughing. Temperature, 99.2° F., pulse 88. The diagnosis of strangulated hernia was made, and the patient was operated on the same day.

On opening the sac about eight ounces of clear, straw-colored fluid escaped, and the sac was then seen to contain an elongated body, about ten inches long and one inch in diameter, which was intimately adherent to it, and which on palpation gave one the impression of a very thick wall surrounding a rather narrow lumen. This body was separated from the sac and an incision was made into it, when it was found that the appendix occupied its center and was surrounded by a thick mass of inflammatory connective tissue. The finger passed through the inguinal canal without difficulty and without encountering any point of constriction.

The appendix was freed of its connective tissue covering, tied off near the cæcum with catgut, and removed, its stump being touched with the Paquelin cautery. The sac was tied off with catgut and removed, and Bassini's operation was done for the cure of the hernia. With the exception of a single suture abscess, the wound ran an aseptic course; the patient being discharged on the twenty-fifth day, with his wound entirely healed, and with no return of the hernia.

Upon examination the removed appendix proved to be 9¾ inches long, and showed at its distal extremity congestion and spots of ecchymosis.

Two points are worthy of note in this case: 1. The unusual length of the appendix. 2. The similarity in the symptomatology of strangulation and an acutely inflamed appendix occupying a hernial sac.

Military-Medical Statistics of the United States Army for the Year 1903.—A supplement to the annual report of the Surgeon General of the United States Army, for the year 1904, has been issued, giving tables as agreed upon at the meeting of the International Commission for the Unification of the Medical Statistics of Armies, held at Budapest in 1894, and modified at the last meeting held at Madrid in 1903. They are calculated for the entire army, American and native, and, except Tables 9 and 10, include officers as well as enlisted men. All the tables except 1, 2, and 8 give both absolute and proportional numbers. Dispositions include cases remaining from last year, but do not include cases remaining at the close of the current year; deaths include suicides and accidents; days lost include those lost this year by cases remaining from last year. Table 1 shows in absolute numbers, by departments, the mean strength of the command, the admissions to quarters, to hospital, and total admissions; the disposition of the sick, total, and the number returned to duty, died and otherwise disposed of, and the total number of days of sickness. Table 2 gives the same data in ratios per 1,000, and also shows the days lost per soldier, and per admission. Table 3 shows by arms of service the mean strength, the total admissions, and those to hospital only, the total disposition, and the number of those returned to duty, and the number that died. Table 4 gives the same data as Table 3, by months. Table 5 shows for each of twenty-two of the larger garrisons the mean strength, admissions to hospital, and total admissions, and the deaths. Table 6 shows for each of the thirty-five diseases or disease groups agreed upon by the International Commission, the number remaining under treatment at the commencement and close of the current year, the admissions and dispositions for the year, the total sick days, and the average number of days per case. Table 7 shows the admissions by arms of service for the diseases and disease groups referred to in Table 6. Table 8 gives the same data as Table 7, by months. Table 9 shows death by rank, by length of service, and by age. Table 10 gives the same data as Table 9 for discharges for physical disability.

Quackery in Germany.—The peculiarity of German law, which makes the practice of the healing art free to all, although there is a penalty for the unauthorized use of the title doctor, causes quackery to flourish to an amazing degree in what in other respects is justly considered the holy land of science. In 1902, according to official statistics, there were in the whole of Prussia 15,400 doctors, and 4,104 quacks. The evil has become so serious that a society was some time ago formed in Berlin for the express purpose of exposing quackery. Under the auspices of this body an exhibition of quackery was recently held in Breslau, where everything pertaining to medical quackery was exposed. Its advertisements, panaceas, various methods of treatment, anti-epidemic masks, universal gastric juices, bogus electrical apparatus, etc., were all on view. In the case of one cult the announcement was made that during the past fifteen years its members had collected from the public over $3,500,000. One section of the exhibition was devoted to methods for suppressing irregular practitioners.—*The Globe.*

Gorillas as Experiment Animals.—The usual laboratory animals have been found inadequate in studying some of the newer features in connection with tuberculosis, syphilis, and the tropical diseases owing their origin to blood parasites. Many medical institutions are anxious to secure gorillas and chimpanzees for this purpose, and the demand is said to have stimulated the collectors of these animals to unusual activity.

A Costly Illness.—It is estimated that the expenses of Lady Curzon's illness have already amounted to something like $50,000, or about one-half her husband's salary as Governor-General of India. Sir Thomas Barlow and one or two other equally famous specialists lived for days together at Walmer Castle, with fees of $500 apiece a day, while each time additional medical attendance or even medicaments were needed from London special trains were employed.—*The Tribune.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THE CARDIAC AND VASCULAR COMPLICATIONS AND SEQUELS OF TYPHOID FEVER.

DR. W. S. THAYER (*Bulletin of the Johns Hopkins Hospital,* October, 1904) has made an analysis from the clinical standpoint of the cases of typhoid fever observed at the Johns Hopkins Hospital during a period of fourteen and a half years, together with a study of the gross pathological lesions, having especial reference to the cardiac and vascular symptoms and complications. As a result he states that typhoid fever is a disease that is often associated with symptoms suggestive of a grave weakening of the heart-muscle. These changes, whether due primarily to the direct action of the typhoid poison on the heart or to impaired nourishment as a result of vasomotor paralysis, result in a considerable proportion of cases in a temporary insufficiency of the mitral valve, as indicated by the appearance of apical systolic murmurs, which not infrequently are transmitted to the axilla. These murmurs develop especially at the height of the disease, during the latter part of the first and in the second, third, and fourth weeks, and disappear usually with convalescence. Sometimes, however, they persist. The average systolic blood-pressure was found higher in every decade among old cases of typhoid fever than in healthy individuals who had never had typhoid fever. So, too, the radial arteries were palpable with strikingly greater frequency in the former than in the latter.

Endocarditis, while not a common complication of typhoid fever, is more frequent than is commonly supposed, while pericarditis is an unusual and unimportant complication. Phlebitis and venous thrombosis constitute a frequent complication. The onset occurs usually in the third week or later, and is in most cases attended with fever, leucocytosis, and local pain. Not infrequently the fever and leucocytosis precede the localizing symptoms. The complication was ushered in or associated with chills in more than one-quarter of the cases. The phlebitis occurs, in the great majority of cases, in vessels of the lower extremity, especially on the left side, and it is particularly common in the femoral veins. The complication is always a serious one, for while the immediate dangers—gangrene, extension of the thrombus, pulmonary embolism—are not great, the after-results are often grave. The affected extremity is always considerably and permanently enlarged, and there is usually persisting disability—extensive varicosities, often resulting in ulceration; marked weakness of the limb; frequent cramps in the muscles, especially at night and after over-exertion. Arteritis and arterial thrombosis constitute a more frequent complication of typhoid fever than is generally recognized. The complication appears to be especially common in the cerebral vessels, although it may occur also in the extremities. It may set in at the height of the disease, but it is commoner in the third week or later. The onset often is attended with fever and leucocytosis. In the extremities arterial thrombosis is commonly followed by gangrene, in the cerebral vessels by hemiplegia. Arteritis in the extremities may be associated with partial parietal thrombosis from which complete recovery may take place. A survey of the pathological material suggests that typhoid fever may be a not uncommon cause of focal arteriosclerotic changes. This idea is further supported by the remarkable frequency with which sclerosis of the peripheral vessels was found in old cases of typhoid fever.

While the deleterious influence of typhoid-fever upon the cardiovascular system is not as great as that of acute rheumatism, yet as a result of the unfortunate frequency of the disease in the United States it is probable that post-typhoid cardiovascular defects are not uncommon. It would therefore be wise for the practising physician to bear this fact in mind, and whenever possible to keep his typhoid patients under observation for several years following the attack.

VALUE OF THE STUDY OF MEDICINE AND OF THE HISTORY OF MEDICINE.

CONAN DOYLE, speaking at Norwich, England, a short time ago, laid great stress on the splendid training that the study of medicine gave to a man. As a school for building up character, for strengthening and accentuating the powers of observation, and for fitting an individual generally for the battle of life, he compared the study of medicine to that of the other professions, greatly to the advantage of the former. He even went so far as to declare that if the officers of the British army were to be so well trained in the profession of arms, as doctors are in their calling, the British army would be the terror of Europe. However, it being an after-dinner speech, a certain amount of latitude in terms must be allowed the speaker. The main argument that the study of medicine is a magnificent training, no matter what may be undertaken later, admits of no doubt.

Dr. Eugene F. Cordell, President of the Medical and Chirurgical Faculty of the State of Maryland, delivered an address on its one hundred and fifth anniversary, the subject matter of which resembled in some degree the speech of Conan Doyle. In the first part of his address he criticised somewhat severely the apathy of university and college authorities with regard to the teaching of medical history to medical students. In support of his contention he quotes the saying of Lord Macaulay that "no man, who is correctly informed as to the past, will be disposed to take a morose or desponding view of the present." The speaker especially deprecated the rage for novelty and the haste, characteristic of Americans, and argued that a knowledge of the past cannot fail to stimulate the young, and work in every way for good. Dr. Cordell thus summed up some of the advantages of the study of medical history: (1) It teaches what and how to investigate; (2) it is the best antidote we have against

egotism, error, and despondency; (3) it increases knowledge, gratifies natural and laudable curiosity, broadens the view, and strengthens the judgment; (4) it is a rich mine from which may be brought to light many neglected or overlooked discoveries of value; (5) it furnishes the stimulus of high ideals which we poor, weak mortals need to have ever before us; it teaches our students to venerate what is good, to cherish our best traditions, and strengthens the common bond of the profession; (6) it is the fulfillment of a duty—that of cherishing the memories, the virtues, the achievements of a class which has benefited the world as no other has, and of which we may feel proud that we are members.

Both of these speakers are to be congratulated upon the manner in which they presented their subject. The training for the medical profession, when properly carried out, is undoubtedly more arduous than that of any other profession. In these days, when competition is keen and the struggle for existence hard, the victory goes to the best equipped for the fray. The individual who has undergone the ordeal of training for the medical profession starts in the race with every advantage, and if he be determined to succeed should not fail to reach the goal. Dr. Cordell's remarks on the good wrought by the study of the history of medicine were illuminative and to the point. There is assuredly too great hurry in these days to be in a position to make money. Everything that does not directly tend to this end is put on one side as useless. The fact is not considered that a knowledge of medical history acts as a spur to endeavor, and assists in forming character which is, after all, of greater importance in the making of a good medical man and citizen, than is an accurate acquaintance with up-to-date medicine.

ANOTHER CANCER SERUM.

The newspapers last week reported, with scare heads, photographs, photomicrographs, and editorial comments, a new cancer discovery from the Gratwick Pathological Laboratory at Buffalo. It is asserted that a number of cures of cancer in mice have been affected by means of a serum prepared at the laboratory, and the hope is suggested that the treatment will be equally efficacious in man. According to the New York *Herald* the cancerous mice used for the experiments were obtained from Professor Jensen of Copenhagen. They survived the Atlantic voyage, but expired between here and Buffalo. The cadavera were preserved and inoculations from one of them "took" on several live mice, and by repeated transplantation a large number of the animals with cancer became available for further experimentation. Many of these mice recovered spontaneously, and the experimenters conceived the idea that this fortunate result was brought about by the elaboration of an antitoxin. Having in mind the possibility of a successful serum treatment of cancer, they conducted a series of experiments which they think have proved beyond question that the blood of mice which have recovered from cancer possesses an antitoxic quality. This blood, when injected into mice suffering with cancer, arrested the growth, and when the tumors were not too large caused their disappearance.

We have no reason to doubt the accuracy of the observation of the workers at the Buffalo laboratory as regards the fact of the disappearance of the tumors in mice treated with serum, and we earnestly hope they may be able to develop their discovery so that it may become applicable to man. But the plans of mice and men are proverbially uncertain in their outcome, and it is deplorable that the secular press should have prematurely reported these incomplete results. Even if the highest hopes of the experimenters are eventually realized, the announcement of their discovery at this time can but do much harm by inducing many present sufferers to cast away the plank of surgical excision to grasp at what is yet but the straw of serum therapy. Schmidt, Doyen, Adamkiewicz, and others whose names we have forgotten have elaborated antitoxic cancer sera, and they have failed to cure. This, of course, is no argument against the possibility of the Buffalo serum being efficacious, but in a matter of such momentous importance to mankind it behoves one to proceed with extreme caution and not to ignore the lessons of the past and the present even while dreaming of a glorious future. Many mountains have been in labor at various times, but, alas, many little white mice have been born.

Cirrhosis of the Liver.

At the recent Congress of German Naturalists and Physicians a discussion was held on the subject of cirrhosis of the liver, the principal speakers being Dr. Kretz, of Vienna, and Dr. Naunyn, of Strassburg (*Münchener medizinische Wochenschrift*, Oct. 25, 1904). The former maintained that granular cirrhosis of the liver is not due to interstitial hepatitis, the parenchyma of the organ being altered by regenerative processes in the sequence of numerous degenerative lesions. The presence of elastic fibers in the connective tissue of the cirrhotic liver is essentially dependent upon the breaking down of transformed highly vascular portions of parenchyma. The primary anatomical alteration at the beginning of the cirrhotic process takes place not in the connective tissue, but in the areas of parenchymatous degeneration and subsequent replacement of regenerated tissue in the most highly vascular portions of parenchyma. Cirrhosis of the liver is not a disease-entity, but the alteration in the liver is the anatomical result of various forms of degeneration of the liver-cells in conjunction with new formation of parenchyma. From the etiological standpoint the morbid process may be superinduced by all pathological influences that cause parenchymatous degeneration; by abnormal metabolic products, by poisons, by bacterial injury. The noxious substance may gain access to the liver-cells by way either of the circulation or of the bile-capillaries.

Naunyn contended that various forms of cirrhosis of the liver are to be differentiated, namely, incipient cirrhosis, ordinary ascitic (atrophic) cirrhosis, biliary (hypertrophic) cirrhosis, and hypersplenic cirrhosis. The distinction between these several forms depends not upon original differences in the morbid process, but upon the complicating cirrhotic cholangitis, which manifests itself in the different varieties in different degree and in different manner. This cholangitis is enterogenous and ascending. It is not the cause of the cirrhosis, but a complication occurring in a liver already the seat of cirrhosis. The rejection of enterogenous and splenogenous forms of cirrhosis is not justifiable. On the other hand, the hematogenous origin of cirrhosis is generally probable. Hemolytic processes may be operative in this connection, and if there is a cirrhogenous cholangitis this may be descending and of hemolytic origin.

Complications of Diabetes.

Diabetes is either becoming more common in this country, or it is more accurately diagnosed than was formerly the case. As, however, it is preëminently a disease of advanced civilization, that is to say, largely consequent upon overeating and drinking and too luxurious living, the fact is more or less obvious that it should naturally become more and more prevalent in these days.

Dr. John E. Clarke writes in the *Detroit Medical Journal* of the complications of the disease. These are legion. The writer refers to the ocular changes produced by the condition, which are more rare than the visual disturbances accompanying renal affections. However, the eyes are affected sufficiently often in diabetes to render a careful consideration of eye symptoms necessary. According to N. L. Pyle the retinal changes in glycosuria differ so distinctly as to be readily determined by the ophthalmoscope, inasmuch as the inflammation of the optic nerve is never present in glycosuria, a condition so prominent in albuminuria, syphilis, and other blood dyscrasias.

Diminution of memory, a growing indifference, loss of aptitude for intellectual work, and a tendency to anger, melancholy, and hypochondria, are classed by Bouchardat, with whom Clark agrees, among the noteworthy complications of glycosuria. Pneumaturia is a rare complication, while gangrene is one of the most alarming complications of glycosuria. Diabetic neuritis is an accompaniment of diabetes which occurs infrequently. Dr. Pavey is of the opinion that the numerous nervous symptoms are exaggerated in proportion to the amount of sugar contained in the urine. This view is not confirmed by Clark.

The Medical Service of the Japanese Army.

The Japanese in many ways have opened the eyes of the Western nations. Their extraordinary aptitude for organization and grasp of detail in the present war have made a deep impression. No part of the military machine has worked with greater smoothness than the medical service of the Japanese army. Major Louis Seaman's book, just published, dealing with the Japanese army in Manchuria, and devoted chiefly to its medical service, affords striking evidence of this fact. A comparison between the deaths from disease, occurring among American soldiers in the Spanish-American war, in the Philippines, and in China, and the mortality from the same cause among Japanese troops, is greatly in favor of the latter. In the Spanish-American war this country lost fourteen men by disease to every one who was killed in battle. In Manchuria Dr. Seaman found that although fighting in a country notoriously unhealthy the fatalities from disease in the Japanese army were extremely small. The treatment of the wounded at the large hospitals was so skillful that the deaths were hardly one in a hundred. The results at the naval hospital were equally satisfactory, although the wounds, as a rule, were of a far more dreadful nature.

Dr. Seaman has also the very highest praise for the arrangements of the hospitals, and especially for the excellent work done by the Japanese nurses. These nurses are very strong physically. The writer declares one of these tiny women will take up a man and carry him upon her back to and from the operating room with apparently the greatest ease.

The Japanese medical officer comes in for unstinted praise at the hands of Dr. Seaman, who is of the opinion that he has no superior, if, indeed, an equal, among his brethren in the armies of Europe. The sanitary methods pursued in the Japanese medical service are exact and careful in every minute particular, and it is undoubtedly largely due to this strict attention to detail that disease has been so successfully warded from the Japanese army. A perusal of Dr. Seaman's book will tend to show that not only has the Japanese medical service successfully imitated the best European models, but has even improved upon them.

News of the Week.

The Manuel Garcia Centenary Jubilee Fund.—At a meeting of the allied committees representing the Section on Laryngology of the New York Academy of Medicine, The American Laryngological, Rhinological, and Otological Society, and the American Laryngological Association it was voted to appeal to the laryngologists throughout the country for contributions not to exceed five dollars each to the Garcia Fund in celebration of the one hundredth birthday of the inventor of the laryngoscope. Payment should be made before February 15 to either of the following: Dr. D. Bryson Delavan, 1 East 33rd St., Dr. M. D. Lederman, 58 East 75th St., or Dr. Harmon Smith, 44 West 49th St., representing the Laryngological Section of the Academy of Medicine; Dr. R. C. Myles, 48 West 36th St., representing the American Laryngological, Rhinological, and Otological Society, or Dr. J. E. Newcomb, 118 West 69th St., representing the American Laryngological Association.

American Public Health Association.—At the meeting of this association in Havana, last week, the following officers were elected: *President,* Dr. Westbrook of Minneapolis; *First Vice-President,* Dr. Juán Guiteras of Havana; *Second Vice-President,* Dr. Lopez of Mexico; *Third Vice-President,* Dr. Macdonald of Brandon, Manitoba.

The Vermont Board of Medical Examiners.—The newly-appointed Board of Medical Registration for Vermont met at Montpelier, January 10, 1905, for organization. The following are its officers and members: *President,* Dr. Henry Janes, Waterbury; *Secretary,* Dr. W. Scott Nay, Underhill; *Treasurer,* Dr. E. B. Whitaker, Barre; Drs. F. H. Godfrey, Chelsea, J. Sutcliffe Hill, Bellows Falls, Sam Sparhawk, Burlington, and A. E. Parlin, Barton Landing. The next meeting of the Board will be held at Burlington for examinations on February 7, 8, and 9, 1905. Application blanks and circulars of information can be obtained from the secretary.

Ohio State Board of Medical Examiners. — This Board organized January 3 by electing the following officers: *President,* S. B. McGarvan, Cadiz; *Vice-President,* H. H. Baxter, Cleveland; *Secretary,* Frank Winder, Columbus; *Treasurer,* S. M. Sherman, Columbus. The number of successful applicants for certificates at the recent State examination was thirty-nine.

Suicide of the Kaiser's Dentist.—Dr. Alonzo H. Sylvester, a well-known dentist of Berlin, one of whose patients and patrons was the German Emperor, committed suicide on January 10. He was born in Maine sixty years ago and was graduated from the Boston Dental College in 1871. Soon after graduation he went to Berlin, where he met with instant and signal success. His practice was very large, but he had recently had financial reverses, and for a few days before his death had suffered from a sharp attack of influenza and had shown great mental depression.

Fewer Street Accidents in New York City.—Police returns on street accidents for last December show a large decrease when compared with December, 1903. The entire number of accidents reported was 221 for December, 1904, as compared with 300 for the same month in 1903, a decrease of 23 per cent. The number of people struck by cars was 32 in 1904 and 55 in 1903; by wagons, 22 and 41. The number of collisions between cars and trucks or wagons was 40 in 1903 and 31 in 1904.

Increase in Railway Accidents.—According to the report of the New York State Railroad Commission, there were 94,522,477 passengers carried within the State during 1904, an increase of more than 5,000,000 over the preceding year. The total number of persons killed was 952, and injured, 2,399. In 1903, 884 were killed and 1,726 injured. The report attributes the increase in casualties during the decade to the greater number of trains operated, for they say improvements in roadbeds and eqtuipment, which should have diminished the number of accidents, have been many. Only 12 of those killed and 446 of those injured in 1904 were passengers. The average for the last five years is 18 passengers killed and 349 injured. During the year 193 persons were killed on street surface roads and 878 injured.

Second Councilor District of the Ohio State Medical Society.—The first annual meeting of this branch of the Ohio State Medical Association was held at Dayton, O., Nov. 17, 1904. Dr. D. R. Silver of Sidney was elected *President,* Dr. F. P. Anzinger of Springfield, *Secretary* and *Treasurer.* Papers were read by Drs. R. H. Grube of Xenia, F. C. Gray of Dayton, A. Boone, B. F. Beebe, B. R. McClellan, D. G. Reilly and H. F. Lorimer. Dr. C. A. L. Reed of Cincinnati delivered an address on "National Medical Legislation." A banquet with toasts followed.

Smith County, Texas, Medical Society.—At the annual meeting of this society, the following officers were elected: *President,* Dr. J. Charles Smith of Starrville; *Vice-President,* Dr. R. H. Urquhart of Tyler; *Secretary* and *Treasurer,* Dr. Albert Woldert of Tyler.

Alpha Kappa Kappa. — The tenth annual convention of the Alpha Kappa Kappa Fraternity, in session December 30 and 31, at Cincinnati, came to a close with a banquet. The election of officers to serve the coming year resulted as follows: *Grand President,* Dr. George Cook, Concord, N. H.; *Grand Vice-President,* Dr. John I. French, Boston, Mass.; *Grand Secretary,* Dr. Edward L. Heintz, Chicago; *Grand Treasurer,* Dr. Edward R. Pfarre, New York City.

The New York State Eclectic Medical Society was in session in this city last week. The annual election resulted in the choice of the following officers: *President,* Dr. W. J. Krausi, New York; *Vice-President,* Drs. R. W. Padgham, Geneva; F. D. Gridley, Binghamton, and M. B. Pearlstein, Brooklyn; *Treasurer,* Dr. D. N. Bulson, Rockville Centre; *Recording Secretary,* Dr. Earl H. King, Saratoga Springs; *Corresponding Secretary,* Dr. G. W. Boskowitz, New York. The next annual meeting will be held in Albany.

Chicago Charity Ball. — The net receipts of the Charity Ball recently held in Chicago aggregated about $25,000, of which the following will receive their pro rata share: Chicago Bureau of Charities, Visiting Nurses' Association, Children's Memorial Hospital, Provident Hospital and Training School, Old People's Home, Chicago Orphan Asylum, Allendale Association, Chicago Home for Convalescent Women and Children, Milk Commission of the Children's Hospital Society of Chicago, Illinois Children's Home and Aid Society, Bureau of Justice, and Home for Destitute and Crippled Children.

Cincinnati Health Report.—The Board of Health report gives the number of deaths in 1904 as 6,975. This is an increase over 1903, when the number was 6,201. The largest number of deaths in any one month was in March, when there were 805. January came second with 763, and February was a close third with 760. During the year the City District Physicians attended 6,250 patients and made 12,468 calls. They reported 60 deaths and sent 367 of the patients to the hospital. The number of school children vaccinated was 1,059.

Cab Drivers Hold Mortality Record.—In the annual report of the Business Agent of the Cab and Carriage Drivers' Union, of Chicago, it is stated that out of a total average membership of 1,200, 70 men have died during the last twelve months. These figures represent more than five times the normal mortality of Chicago. Six men have died in the last two weeks, and 35 are so ill that they are being paid benefits by the union.

Wood Alcohol Legislation.—A bill is being prepared for introduction into the New York State Legislature which, if it becomes a law, will, it is believed, prevent the adulteration of whiskey with wood alcohol. The bill provides that all manufacturers who make wood alcohol shall submit annual reports of sales to the State Department of Health. Proper inspection and sale restrictions are also to be provided for in the bill.

Care of Consumptives.—The Board of Health of Paterson, N. J., has determined to take up the question of declaring tuberculosis a notifiable disease and of providing for the isolation and care of persons suffering from this affection. A special meeting will be called for the consideration of this matter.

Dr. Samuel Iglaur has been elected Secretary of the Cincinnati Academy of Medicine, to fill the unexpired term of Dr. Stephen E. Cone, who resigned a few weeks ago.

Dr. Francis D. Patterson has been elected surgeon to Howard Hospital, Philadelphia, in succession to Dr. Charles H. Frazier, resigned.

A Village Without a Doctor.—A Village Health Board has been organized in Kennedy Heights, Ohio, with A. O. Stanley, President, and Louis Niedermeyer, Clerk. As there is no physician residing in the village, the board has asked the State Board of Health if a physician living outside the village can be appointed Health Officer.

Cincinnati Water Works.—Up to date Cincinnati has spent $5,113,296.83 on her new Water Works plant and it is estimated that two more years will be required for its completion.

Hospital News.—*A New Red Cross Hospital.*—William T. Wardwell, ex-Treasurer of the Standard Oil Company, has given $100,000 for the building of a new Red Cross Hospital. The hospital will be situated on the heights of Fort George, near the upper end of Manhattan Island. The entire cost of the new building and its equipment will be between $350,000 and $400,000. The names of other donors besides Mr. Wardwell have not been made public yet, but there have been several large gifts, and the Trustees anticipate no difficulty in raising the necessary amount of money. The present hospital of the Red Cross is on Eighty-second Street just west of Columbus Avenue. It is small and not equal to the needs of the organization. One of the features of the new hospital will be a large training school for nurses with a constant attendance of between one

and two hundred. Every nurse who joins the Red Cross promises to hold herself in readiness for any war, riot, or insurrection, even if she has left active hospital work. The plans of the new building are already in the architects' hands, and it is expected that ground will be broken very soon.

Fire in a Montreal Hospital.—The administration building of the Royal Victoria Hospital, on the brow of Mount Royal, Montreal, was injured by fire on January 14, and damage to the amount of $150,000 was done. The fire was confined to the central building, and the pavilions on either side were at no time in danger. The Royal Victoria Hospital was built about twelve years ago at a cost of more than a million dollars, and was the joint gift of Lord Mount Stephen and Lord Strathcona. It is the largest and finest in Canada.

The Cincinnati Hospital.—The number of patients treated in this hospital during the year 1904 was 9,224, as compared with 7,294 treated in 1903. The daily average of patients in the institution was 573 in 1904 and 493 in 1903, and the total number of days of treatment was 209,988 in 1904, and 179,945 in 1903.

The New York State Hospital for the Care of Crippled and Deformed Children will ask the State Legislature for an appropriation of $200,000 for the erection of a modern hospital building on the farm of fifty acres which has been purchased at West Haverstraw, Rockland County, and where the hospital will be installed in an old Colonial farmhouse in April next.

Bellevue Hospital Training School.—Sixteen young women received diplomas at the graduation exercises of this school on the evening of January 9. An address was delivered by Prof. William M. Sloane of Columbia University.

Cook County Hospital Staff.—The following is the new staff at Cook County Hospital, which has just been appointed by President Brundage: *Regular Staff.* Medicine—R. H. Babcock, W. S. Harpole, Charles L. Mix, R. B. Preble, S. R. Slaymaker, Camillo Volini, M. L. Goodkind, J. B. Herrick, J. F. Miller, B. W. Sippy, Frederick Tice, E. F. Wells. Obstetrics—R. W. Holmes, Charles B. Reed, H. F. Lewis, Rachelle Yarros. Children's and Contagious Diseases—W. L. Baum, Isaac A. Abt, Frank X. Walls, F. B. Earle, F. S. Churchill, George H. Weaver. Nervous and Mental Diseases—Sidney Kuh, Julius Grinker, L. H. Mettler, H. N. Moyer. Surgery—E. Wyllys Andrews, A. I. Bouffleur, Charles Davison, D. N. Eisendrath, Wiliam Hessert, F. A. Besley, T. A. Davis, B. B. Eads, A. E. Halstead, F. S. Hartman, C. E. Humiston, Charles W. Heywood, O. W. MacKellar, M. L. Harris, A. P. Heineck, W. E. Schroeder. Eye, Ear, Nose and Throat—William E. Gamble, Frank Allport, Brown Pusey, G. P. Marquis. Skin and Venereal—L. Lake Baldwin, William A. Pusey. *Homeopathic Staff.* Surgery—Charles E. Kahlke, B. A. McBurney, F. E. Titzell, G. M. Cushing, E. E. Vaughan. Obstetrics—G. Fitzpatrick. Eye, Ear, Nose and Throat—B. Haseltine. Children's and Contagious Diseases—A. M. Cameron. Medicine—H. V. Halbert, F. Wieland, A. R. McDonald, F. W. Wood. *Eclectic Staff.* Surgery—Hugo E. Betz, A. C. Kubicek, W. R. Schussler, W. H. Hipp, J. D. Robertson. Medicine—N. A. Graves, A. H. Reading, M. C. Korb, F. E. Thornton. Children's and Contagious Diseases—J. A. Jennings. Obstetrics—C. H. Bushnell. Eye, Ear, Nose and Throat—Charles H. Francis.—*General Science.* Pathology—Wiliam A. Evans, E. R. Le Count. Dentistry—M. J. Conley. Pathological Chemistry—R. W. Webster. Orthopedic Surgery—J. L. Porter. X-Ray—E. A. Fischkin. The following officers were elected by the new staff: *Chairman,* Dr. W. L. Baum; *Vice-Chairmen:* Drs. L. Blake Baldwin, H. V. Halbert, and Hugo E. Betz; *Secretary,* Dr. Chas. E. Kahlke.

New Manhattan Eye, Ear, and Throat Hospital.—Plans have been filed at the Building Department for a new nine-story building to be erected at 208 to 216 East Sixty-fourth Street, for the Manhattan Eye, Ear, and Throat Hospital, now at Park Avenue and Forty-first Street. The new structure will stand on a plot 118 by 100. Two wings on the main structure will provide sun parlors on each of the nine stories. The façade will be of ornamental brick with trimmings of stone and terra cotta.

Hospital Endowment.—Mr. Samuel M. Fridenberg has donated $5,000 to the Jewish Hospital of Philadelphia for the endowment of a room in memory of the late Mrs. Fridenberg.

Free Beds.—By the will of the late William S. Bunting the sum of $500 is bequeathed to the Episcopal Hospital of Philadelphia to go toward the establishment of a free bed. A like sum is left to the Home for Incurables for a similar purpose.

Obituary Notes.—Dr. Thomas H. Manley of this city died on January 12 of pneumonia after a brief illness. He was born in New England about fifty-five years ago and was graduated from the New York University Medical School in the class of 1875. Dr. Manley was an indefatigable student, a conscientious and careful surgeon, and a voluminous writer; and few medical men had a wider acquaintance throughout the country, for he was a member of many societies, a frequent attendant at the meetings, and a ready debater. He was visiting surgeon to the Harlem and Metropolitan Hospitals.

Dr. Henry Martin Wells, Medical Director, U. S. N., retired, died in this city on January 12 at the age of seventy years. He was born in Massachusetts, and entered the service in 1861, being first attached to the Naval Rendezvous and Hospital at Boston. He served in the West Gulf blockading squadron during the first two and a half years of the war. He was in the actions against Forts Jackson and Saint Philip, under Farragut. In June, 1864, he was promoted to be Passed Assistant Surgeon. While serving in the Brazil squadron from 1865 to 1868 he was commissioned a surgeon. After serving on a number of ships up to 1880, Dr. Wells engaged in the service at the Naval Observatory and Hospital in this city. In 1884, at the conclusion of this service, he was made Medical Inspector, and for a time was in charge of the Museum of Hygiene in Washington. In 1891 he was commissioned Medical Director, and in January, 1897, he retired.

Dr. William Harper Davis died at his home in Brooklyn on January 8, of Bright's disease, at the age of thirty-two years. He was born in this city and was graduated from the Eclectic Medical School in 1896.

Dr. Henry E. Woodbury of Washington, D. C., died in that city on January 15, at the age of seventy-nine years. He was born in New Hampshire and was graduated from Dartmouth College. He studied medicine in Washington, receiving his degree of M.D. from the Medical Department of the University of Georgetown in 1863. He at once entered the army as assistant surgeon and served until the close of the civil war when he settled in Washington and practised there for many years until disabled by an accident.

(From Our Special Correspondent.)

SUDDEN DEATH IN CHILDREN—EFFECTS OF GRAFTING OF THE THYMUS—COLCHICINE—ENGORGEMENT OF LUNG FROM ALTERATIONS OF THE SYSTEMIC CIRCULATION—NOTES—OBITUARY.

LONDON, December 30, 1904.

Sudden or unexpected death in children is every now and then an inexplicable circumstance and causes as much surprise as the equally unaccountable recoveries that sometimes occur, or the escapes from what seems inevitable death in accidents and which have given rise to the proverb, that a special Providence is over them. The equally appropriate saying that children are apt to slip through the doctor's fingers seems also derived from observations of cases of sudden death in these fragile patients.

A discussion on these cases was held on the 16th inst. It was opened by Dr. C. J. Macalister of Liverpool, who dealt mainly with such as appeared to him to be due to some toxic influence. He referred to the fact that such cases are met with in institutions for the care of children and quoted cases in which, after only a few hours of headache, vomiting, or diarrhea, the little patients sank rapidly in a cyanosed condition. At the autopsy there might be a mere patch of lung consolidation, but he had met with no nerve lesions and thought some toxin attacked the respiratory center. In a school where collective bathing was in use, some five years ago, several deaths of the kind occurred, but ceased on discontinuance of that practice, and he remarked how saturated with organic matter the water became after a number of children had been washed in it. Dr. Macalister mentioned another type of death, instancing a case of a healthy child dying with appalling suddenness, which he felt disposed to ascribe to infantile paralysis attacking the center of the vagus, and he seemed inclined to attribute this to some flaw in the nursery hygiene. Hemorrhages he also referred to as the cause of the toxemia. Some cases may have been typhoid, others diphtheria, or cardiac disease, masked by different conditions.

Dr. Porter Parkinson referred to cardiac failure, convulsions to the extent of asphyxia, laryngismus, glottic spasm, and other causes. "Overlaid babies," no doubt, often died from asphyxia. Emotion he regarded as a rare cause, though it may be objected that terror has terminated fatally many times.

Dr. Thomson Walker dwelt on the clinical picture of the status lymphaticus as showing: (1) No evidence of previous illness, but (2) previous restlessness, etc.; (3) thymic asthma. Rickets is often present. Some still-births and deaths from anesthesia or shock might be thus accounted for. Hyperplasia of the heart, coarctation of the aorta, enlarged thyroid, etc., have been found.

Mr. Tubby spoke of hemorrhages and hemophilia, scurvy, ulcer of the stomach, or duodenum, thrombosis, and so on. Also of shock from operations, especially irrigation of the pleural cavity, which he attributed more to the nature of the fluid used than to the actual washing, provided there was free exit for the fluid. Other causes were connected with the larynx and trachea. Tying the hands of a restless child was hazardous.

Dr. Blumfield referred to the deaths during or after anesthesia, and urged the importance of securing the services of a skilled anesthetist. Death in the pre-anesthetic stage was almost always absolutely sudden and was due to a too strong vapor of chloroform.

Dr. Page said sudden death in the course of a chronic disease, such as phthisis, might sometimes occur from autointoxication, the patient having been living for a time on the brink of a precipice, so to say.

Dr. Young thought lymphatism more frequent than commonly supposed, both in adults and children. Sudden death was rather frequent in exophthalmic goitre, especially after operation; also in myasthenia gravis with persistent thymus. He had found the thymus persistent in several cases of sudden death.

Dr. Cantley remarked on the importance of the subject to general practitioners. Such cases came under their notice, and they had to make the autopsy and give evidence before the coroner. He mentioned two cases ascribed to mesenteric disease and typhoid, in neither of which did he think the history or post-mortem examination justified the diagnosis. In marasmus some died from syncope, others from a slight convulsion; in many no cause could be stated.

Drs. Guthrie, Pernet, and Edmunds spoke of congenital syphilis, the rapid cure of extensive eruptions, of skin-grafting, etc., each of them contributing some salient point to an interesting discussion on a subject deserving further investigation.

At the Pathological Society, on the 20th inst., Drs. Dudgeon and Russell gave an account of the effects observed of intraperitoneal grafting of the thymus of young animals into other animals of the same species and the same litter. One kitten, one rabbit, and four puppies were grafted. They concluded that the grafting (1) did not affect the health of the animal; (2) did not produce marked blood changes; nor (3) overgrowth of lymphoid tissue in the body; nor (4) changes in bone marrow, liver, or spleen. But (5) the grafted thymus became attached to the peritoneum of intestine, omentum, or abdominal wall, speedily degenerated, and eventually was represented by a small mass of fibrous and adipose tissue. In two of the dogs severe rickets developed, with marked changes, but this was attributed to other circumstances, as the control animal was not affected.

Another communication was by Dr. W. S. Dixon, on the effects of colchicine on the leucocytes. It was very marked degeneration, many becoming swollen, the nucleus indistinct, and the granules were excluded from the cell. Eventually these degenerated leucocytes passed to the lung and bone marrow. An increased mitosis was observed in the marrow. Some observations on the effects of colchicine in man had been made, but were not complete.

A further communication was by Drs. Brodie and Dixon, on alterations in the systemic circulation, which tend to produce engorgement of the lung capillaries. They found the volume of the blood in the lungs diminished by cardiac inhibition and increased by cardiac acceleration. These cardiac changes had more effect on the volume in the lungs than any other interference with the vascular system. The circulation of the lung was passive. It behaved according to the amount of blood sent to it by the right, or taken from it by the left, side of the heart. But there was no evidence that the lung acted as a reservoir. No evidence was forthcoming that adrenalin constricted the lung vessels, although the idea had led to its trial in hemoptysis. Its action is to constrict the peripheral circulation and secondarily stimulate the heart. The volume of blood in the lung is in this way increased. Therefore, the drug should not be given in hemoptysis. Ergot produces a rise in the pressure and increases the volume of blood in the lungs, and digitalis also causes a rise in the pulmonary blood pressure and an increase in the volume, which constricts the systemic vessels.

Dr. A. Morison commented on the decrease of blood pressure by venesection, comparing it with the increase of volume recorded in one experiment by injecting a small quantity of blood into the portal circulation.

Sir Wm. Taylor is succeeded as director-general of the Army Medical Service by the deputy director-general, Lieut.-Col. (temporary surgeon-general) A. Keogh, M.D., C.B.

Dublin University has conferred its honorary M.D., M.Ch., on Sir F. Treves, and its honorary D.Sc. on Major Ronald Ross.

The King has granted the title of Royal to the Victoria Hospital for Consumption, Edinburgh.

Col. W. F. Stevenson, M.B., C.B., R.A.M.C., has been appointed honorary surgeon to the King, *vice* the late Surgeon-General Jameson.

Mr. T. Crisp English, F.B.C.S., B.S., Lond., has been elected assistant surgeon to St. George's Hospital.

Mr. A. Quarry Silcock, surgeon to St. Mary's Hospital, and to the Ophthalmic Hospital, died on the 19th inst., after an operation for appendicitis. He had a very brilliant career, of which he was beginning to enjoy the full fruits, but has passed away at the age of 49. He was a University College student, whence he graduated in medicine and surgery at the London University. Having served the house appointments at his hospital, and there being no probability of a vacancy on the staff, he went to St. Mary's as pathologist in 1884, and speedily made his mark as a skillful surgeon, apt teacher, and a highly equipped observer. The first vacancy on the staff was his, and he had served hospital and school so well that both feel his is a most serious loss. So do his colleagues at the Ophthalmic, where his operative skill and surgical judgment were most highly esteemed.

Fleet-Surgeon (retired) Dr. F. H. Blaxall died on the 23d inst., aged 79. He entered the navy in 1848, served in the Baltic, in the Russian war, receiving the medal; became fleet-surgeon in 1869. His M.D. was of St. Andrew's, 1861. After leaving the navy he was for many years an inspector for the local government board.

Brilliant Surgeons Not Wanted.—Writing in the *Young Man*, Sir Frederick Treves says: "Genius is some sort of neurosis, an uncalculated nervous disease. The few men of genius I have met were exceedingly impossible persons. They are certainly entirely out of place in the medical profession, where even cleverness is not to be encouraged. Indeed, of all desperately dangerous persons the brilliant surgeon is the most lamentable. Cleverness finds its proper field not in the operating theatre, but at the Egyptian Hall."

OUR VIENNA LETTER.

(From Our Special Correspondent.)

NATURE OF ROENTGEN-RAY ACTION—BACTERIOLOGICAL DIAGNOSIS OF TUBERCULOSIS—GASEOUS TENSION OF THE BLOOD—HYPERTROPHY OF THE SEXUAL ORGANS OF THE FETUS DURING THE LATTER STAGES OF PREGNANCY.

VIENNA, December 24, 1904.

DR. ALFRED EXNER has reported a series of animal experiments undertaken to investigate the nature of *x*-ray action. Some time ago Schwarz put forward the view that radium rays decompose lecithin, and Werner has recently shown that this substance after exposure to radium produces the manifestations of radium dermatitis when injected intracutaneously. This suggested the question of whether the phenomenon would hold good for the *x*-ray also, and it was found that lecithin in water exposed to the action of *x*-rays for considerable periods of time gave evidence of decomposition products by the development of color changes and an acrid odor. Ten per cent. solutions of lecithin which had been subjected to this preliminary treatment when injected intracutaneously into rats gave rise, at the expiration of six days, to falling of the hair followed by ulceration of greater or less intensity according to the amount of material used. The same result followed when the *x*-rayed lecithin solution was sterilized by boiling before use, while control experiments with untreated lecithin showed that this was entirely harmless. Dr. Exner expects to be able to make this decomposed lecithin of therapeutic value.

Dr. Honl in discussing the bacteriological diagnosis of tuberculosis, said that simple or combined bacteriological methods enable the diagnosis to be made in stages in which the physical signs are still inconclusive. Demonstration of the tubercle bacillus affords proof positive of the tuberculous nature of the disease but fallacies must be guarded against, and the author described three cases in which other organisms simulated the tubercle bacillus. These were instances of gangrenous pulmonary lesions and gangrenous sinus phlebitis in which tubercle bacilli-like, acid-fast organisms were found which, injected into animals, produced only suppuration and not tuberculosis. Honl, in 1892, proved the existence of thread-like bacilli which are acid-fast like the tubercle bacillus and of which some elements appear more resistant than others. These properties belong to actinomyces, cladothrix acteroides, and cladothrix facinica, whereas the nonpathogenic varieties of cladothrix do not possess this peculiarity. In staining saccharomycetes from cultures it is also possible to prove that some long threads are also acid-fast. In cases with doubtful symptoms and in those in which it is not possible to find tubercle bacilli the old tuberculin may be employed, and if neither of these methods should prove feasible the bacteriological diagnosis may be made by means of the Arloing-Courmont serum reaction.

In the Society for Internal Medicine, Dr. Schrötter reported on the results of some observations on the gaseous tension of the blood and on cardiac work, made in conjunction with Professor Löwy of Berlin. By the introduction of catheters into the deeper air passages, the isolation of certain portions of the lung, and the removal of portions of the pulmonary gases, it was found possible to determine the tension of the blood gases. The following results were obtained:

(1) The elasticity of the lung is so great that the removal of even considerable quantities of air from isolated portions does not at all alter the pressure in them. (2) The occlusion of even large lung areas does not necessarily change the oxygen content of the arterial and venous blood. (3) In the interchange of gases between pulmonary air in isolated portions of the lung and venous blood, the composition of the air approaches the gaseous tension of the venous blood. (4) The oxygen tension of the venous blood averages 5.3 per cent., or 37.5 mm. Hg. (5) The carbon dioxide tension of the venous blood averages 6 per cent. or 42.2 mm. Hg. (6) The nitrogen tension is about 89 per cent. (7) The venous blood is saturated to about 60-65 per cent. in relation to the atmospheric air. (8) The consumption of oxygen by the tissues in absolute terms is 19 per cent. for the arterial blood and 12.5 per cent. for the venous blood, equal to 6.5. c.c. from 100 of blood, and corresponding to 34 per cent. of the arterial oxygen. (9) In an individual weighing 60 kilograms, in a state of rest 3.8 liters of blood circulate per minute, that is, 64.2 c.c. per kilogram. The amount per second and kilogram of body weight is 1.4 c.c. (10) In man the period of circulation is about 72 seconds. (11) The systolic volume of the human heart may be estimated as equal to 55 c.c., that is, 1-1,200 of the body weight, or 1-84 of the blood volume. (12) The circulating activity of the heart is 2.3 per cent of the total cardiac work. (13) The total cardiac work of an individual of 60 kilograms at a blood pressure of 100 mm. averages 7.11 mkg. per minute; or per systole, at a pulse rate of 70, .102 mkg. or 102 grams. The cardiac work per kilogram of body weight equals 118 grams per minute. (14) In order to propel 1 c.c. of blood 1.8 grams of work is necessary. (15) The heart work for twenty-four hours is equivalent to 10,000 mkg., which is equal to 3.6 per cent. of the total energy output. The ratio of the heart work to respiratory work is as 1 to 2.4. Both together therefore, amount to 10 per cent. of the daily consumption of energy. The heart requires 9.24 c.c. of oxygen per minute and 13 c.c. of oxygen per systole when the pulse rate is 70. The coronary arteries receive per minute at least 139 c.c. of blood, i. e., the blood supply of the heart is at least seven times larger than that of the rest of the body when at rest. The following additional facts are of importance from a practical standpoint. Pulmonary hemorrhage is not to be feared even when well marked negative pressure is present in isolated portions of the lung. In the resting condition large portions of the lung may be thrown out of function or the main bronchus be occluded without the production of any change in the blood pressure or volume of ventilation. There is no danger of atelectasis of the lung even after protracted isolation, extending to forty minutes, of portions of the organ. The pressure of a metal catheter for this length of time in the deep air passages is unattended by danger.

Dr. Halban presented before the Society of Physicians of Vienna a communication on the hypertrophy of the fetal organs during pregnancy, and their puerperal involution. The observations showed that just as the organism of the mother undergoes peculiar changes during pregnancy, the organs of the female fetus present almost analogous alterations. The breasts of the fetus from the eighth month on, show histological changes very similar to those present in the mother, and the fetal uterus begins to hypertrophy at this time. A well marked state of congestion is present and the mucosa manifests phenomena comparable to those seen in menstruation. According to the intensity of the reaction all stages are observed from the premenstrual hyperemia to the subepithelial hemorrhages, and the discharge of blood into the cavity of the uterus where blood may always be found on microscopic investigation. In the most severe grades of reaction the well known genital hemorrhages of the new-born are produced. Numerous control studies proved that the phenomona in question represent a physiological reaction and are not due to morbid processes such as asphyxiation, infection, etc. The changes are due to a reaction to active pregnancy substances, and while the maternal uterus responds by the formation of a decidua, the less susceptible fetal organ undergoes only the changes of menstruation. Various considerations seem to indicate that these active substances originate in the placenta, which appears to be the source of a species of internal secretion which is given off both to the mother and child, and produces organic changes. After the birth the influence of the placenta is removed from both organisms so that they no longer receive these substances and puerperal involution takes place in both mother and child. The involution of the breasts and uterus of the child is complete about three weeks after birth. These placental bodies affect not only the feminine sexual system but also that of the male. The breasts and prostate of boys show similar pregnancy reactions, manifested by histological changes and hypertrophy, and a puerperal involution. The active pregnancy substances in addition to their protective action on the sexual organs, also, as is well known, possess toxic side effects which produce renal changes, leucocytosis, and fibrin increase in the blood. These occur in the fetal organism just as in that of the mother and disappear from both when the toxic action of the placenta has ceased after birth. Since eclampsia represents only the severest grade of an intoxication present in greater or less degree in normal pregnancy it is logical to look for the source of this intoxication in the placenta.

Glasgow's Isle of Drunkards.—The Glasgow corporation is considering a scheme under which Glasgow's chronic inebriates shall be banished to the Islet of Shuna, one of the Hebrides group. This islet is leased to a farmer and has been practically forgotten by the corporation of Glasgow, who have owned it for a century. It is sandwiched between the coast of Argyllshire and the Island of Luing, and is only three miles in length and about half that extent in breadth. The climate is described in the corporation reports as similar to that of Jersey, and those who are urging that the islet should be used as an inebriates' settlement point out that the islanders would be practically self-supporting.—*St. James Gazette.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, January 12, 1905.

The Systematic Use of Work as a Remedy in Neurasthenia and Allied Conditions.—Herbert J. Hall, in speaking of the etiology of neurasthenia, remarks that in very many, if not in all cases, it will be found that unusual worry or a tendency to overestimate the importance of small things, or some equivalent mental perversion, existed long before the well-known symptoms of neurasthenia appeared. Worry is a real thing, and it will, if long continued, breed in the sanest mind a dangerous unrest and happiness. Worry is often not distinguished from the mental or muscular fatigue which follows long and arduous labors. The idea is gaining ground that neurasthenia may be largely or wholly psychic. When neurasthenia is established, a feeling of fatigue is often brought on by the mere thought of exertion or by the anticipation of any task. With these ideas in mind, the writer has founded a School of Handicraft, where neurasthenics are taught to work. Pottery, weaving, and basket-making are all taught there. All evident sources of fatigue, such as eyestrain, are eliminated as far as possible. When the patient first presents himself, he is put to bed for a few days, perhaps a week. He is soon asked to do something—without any warning—it may be to sit up in bed. A very gradually progressive program is written out each day, and intrusted to the nurse who carries it out exactly. Anticipatory fatigue and worry are thus almost entirely eliminated. The hours of rest are gradually made shorter, and the hours of work longer, until the day is full of interesting work; the patient forgets himself, and there is no longer need of prolonged rest. Pride and satisfaction in work, and in life, and self-forgetfulness are the great ends to be attained. The products of the shop are worthy of attention, and when they have reached commercial value, they are sold and the proceeds credited to the maker. Although the work is still in the experimental stage, the writer has seen enough of its happy results to feel reasonably sure that this method of treatment will give fairly quick results. He hopes by it to reorganize the life of the individual on better lines, and lead him up to a life of usefulness to himself and others.

Observations on Experimental Drainage of the Peritoneal Cavity of Cats.—Fred T. Murphy has conducted a series of experiments to determine the time which elapses between the introduction of the drain and the formation of walling off sufficiently strong to prevent the drainage of the peritoneal surfaces not in direct approximation to the drain. The experiments were made on cats, and different materials were used to determine their relative value. The gauze and cigarette drains failed to drain the general cavity after about 18 hours, and the rubber dam and glass tubes after about the third 24 hours. The difference in time represents the difference in stimulating effect of the various materials on the peritoneum. The omentum was in all instances the active agent in the process of walling off. There was a single example of general purulent peritonitis, which illustrates a condition of the peritoneum comparable to a sloughing infected wound, elsewhere in which the power of normal reaction of the tissues on the surface has been destroyed, and in which the drainage was useless. The writer concludes from the results of these experiments that it is difficult to see how the presence of normal salt solution can materially effect the formation of adhesions. Disregarding the effect on hemorrhage, and the pain of removal, and considering only the effectiveness of the drain as such, it would seem that the usual drainage materials might be separated into two groups, each having special advantages when used in its proper field. When it is desired to make a given septic area extraperitoneal as quickly as possible, the materials which are walled off within the first 24 hours, would be indicated. In cases in which it is necessary to drain the general septic cavity for as long a time as possible, the group of materials which is walled off only after about the third 24 hours, would be preferable. Theoretically, drainage would be of great value in cases in which it is desirable to make a limited septic area extraperitoneal. The value of a drain as a drain of the general septic cavity after about 72 hours, could not be demonstrated.

New York Medical Journal, January 14, 1905.

A Clinical Study of Myoidema with Especial Reference to Its Occurrence in Pulmonary Tuberculosis.—H. L. Shively refers to a peculiar muscular contraction which may occur in the shape of a ridge at right angles to the muscular fibers about the point of impact, and which is very usually present in cases of tuberculosis of the lungs. It continues for a few seconds and then subsides. This is the nodular form. A fascicular form appears on tapping, in the shape of a longitudinal form which follows the course of the muscular fibers. The first form is a contraction, but the second is, according to the writer, a relaxation. In his experience the nodular form is best noticed in the biceps and the fascicular form in the pectoralis major. No constant or characteristic variations have been noted in the electrical inability of the muscles affected, and in no case has the reaction of degeneration been obtained. As regard its diagnostic value, Shively notes that in a series of 750 cases of pulmonary tuberculosis, it was present in the great majority, and is usually obtained in the incipient stage. It is, therefore, of some importance as an addition to the syndrome of signs and symptoms, making the early diagnosis less difficult.

Differentiation in the Diagnosis of Non-deforming Club Foot.—J. J. Nutt notes that this condition is often mistaken for articular rheumatism, lumbago, gout and sciatica. It may exist for years without structural change, but usually one of two results follow: With a considerable shortening of the gastrocnemius, the plantar fascia likewise is shortened, and an equinus with slight cavus exists; or, if the gastrocnemius is shortened but slightly, the plantar tissue yields to the undue strain, lengthens, and the mediotarsal joint, thus deprived of this bowstring protection, gives way, and flat foot is present. Pain may be of value in the diagnosis. In non-deforming club foot, it is usual for the pain to increase by continued use, and it may be felt in the calf, back of knee, or thigh, and even as high as the buttock. In flat foot the pain is usually worse after rest, and is generally lessened after use. Another cause of a shortened gastrocnemius is anterior metatarsalgia or Morton's neuralgia. This, with a shortened plantar fascia would tend to dislocate the metatarsal bones, and this tendency would be increased by the strain placed on the extensor longus digitorium. Inflammatory disease of the ankle and mediotarsal joint, muscular spasm or ankylosis may be present, those muscles being affected which act on the articulations, but there is no spasm in soleus or gastrocnemius. This history is of value both in this and disease of the mediotarsal joint, and in inflammations of the tarsal bones. In non-deforming club foot the history dates back to an uncertain period and pain with callosities are the chief, usually the only symptoms. In these inflammatory conditions of the joints and bones, the beginning of the trouble is most frequently asserted to be due to some injury, and the pain is often of less moment to the patient than the lameness. Many mistakes result from slipshod methods of examination, but among possible causes to be considered in obscure and unexplained pains in the lower extremity, buttock or small of the back, non-deforming club foot must not be forgotten.

Tic Douloureux and Other Neuralgias from Intranasal and Accessory Sinus Pressures.—S. F. Snow has treated twenty chronic cases of this affection. He has seen none requiring nerve excision for relief, but every one had well marked intranasal pressure or some sinus accumulation, more often the latter. From his personal experience, he is inclined to believe that a pain shooting from the bridge of the nose outward and upward indicates an involvement of the anterior ethmoids. A deeper and more intense pain under or behind the eye, and sometimes apparently in the ear or temple, points to the middle and posterior ethmoids; while a still deeper, splitting pain, radiating outward from the center, sometimes reflected around the anterior third of the lower jaw, is relieved by opening the sphenoid. Accumulations within the maxillary antrum are diagnosticated by the localized pain, with sometimes intense muscular tremor and successions of spasms, shaking the head from side to side. Snow is inclined to believe that 80 per cent. is a modest estimate of the cases of tic douloureux due to the causes named in the title of his paper.

Medical News, January 14, 1905.

Care of Puerperæ.—James D. Voorhees believes that the physician cannot be too conservative in his management of the puerperal woman. A continued asepsis after delivery, is of the greatest importance. The nurse to whose lot this falls, should regard the vulva and the nipples in the light of clean laparotomy wounds, and use corresponding precautions. For the first two or three days, the writer advocates the use of a piece of gauze, wet with a 1-10,000 bichloride solution, placed over the vulva beneath the sterile vulva pad. These dressings should be changed and the parts cleansed at any rate every 4 hours, for the first two or three days. The patient demands a refreshing sleep directly after delivery. If this does not come naturally, chloral, by rectum, seems to act most effectively. Afterpains can be limited as a rule by proper massage of the uterus, by expression of clots, and by the administration of ergot directly after the expression of the placenta. Fluid diet should be given for 48 hours after labor, or until the bowels move. A cathartic should be given on the morning of the third day, followed by an enema, if necessary. As to abdominal binders, if patients are troubled by them, they may be discarded after the third, fourth or fifth day, especially if there is little reason to fear a relaxation of the

abdominal walls. The nipples should receive the most careful attention. They should be cleansed before and after nursing with boric acid solution, and then anointed with albolene. They should then be covered by sterile lint dressings, kept in place by the breast binder. The patient should be cautioned not to touch the nipples. Thus, germs can be excluded, and the greatest predisposing cause to mastitis avoided. Massage will relieve distention of the breasts. Cathartics are invaluable to carry off fluids. Codeine may be necessary to produce sleep. The patient should be kept in bed at least two weeks, and she should be slow in walking. If involution is delayed, hot vaginal douches, boroglyceride tampons, ergot, quinine, and strychnine are valuable. A routine vaginal examination should always be made before a case is discharged.

Trauma and Chronic Compression of the Epigastrium as Etiological Factors of Gastric Ulcers.—William Ackermann cites a number of cases in order to indicate the importance of epigastric compression in gastric ulcers. In 125 consecutive cases of ulcer treated, 28 occurred in males, and 97 in females. The majority of the latter occurred between the ages of 20 and 35 years. The greater number of these females were employed as seamstresses. On account of their occupation, they lead an indoor life, predisposing them to chlorosis or anemia, and this, combined with the pressure of corsets in bending over their work, the writer points out as being the cause of their disease. He states that the frequency of ulcers in the male in the later years of life, can be attributed to the compression of the epigastrium caused by occupation. There are, among the cases reported, several kinds of "occupation compression." There are those cases in which the continual pressure is exerted, such as exists among shoemakers, basket-makers, and so on, caused by the "last" and "willows" respectively. Again, there is the temporary pressure caused by heavy weights resting on the epigastrium, such as teamsters are exposed to; and finally, there is the compression to which such workmen as tailors and bookkeepers are subjected to from their habitual stooped position while at their work. This question is a most interesting one, and worthy of careful consideration, although clinical experience in relation to gastric ulcers, caused by trauma or by long-continued pressure of the gastric region, without injury to the external abdominal walls, is still very limited.

The Nervous Symptoms Accompanying Pernicious Anemia.—Roy M. Van Wart calls attention to Addison's description of pernicious anemia. He mentions nervous symptoms, which at the present time would be called neurasthenia. Later, cases were published, reporting organic changes. Still later, degenerative changes were noted in the brain in pernicious anemia. The symptom-complex presented by the degenerations in the spinal cord in these cases, has been described as a separate disease under the name combined sclerosis. In cases complicating pernicious anemia, the posterior tracts are involved earliest, and the disease may not extend beyond this. There is great difficulty in clinically classifying the forms met with. Cases of spinal cord lesions, accompanying pernicious anemia, may or may not, present symptoms. Again, spinal cord symptoms may antedate the presence of anemia. The etiology of these lesions, as well as that of pernicious anemia, is still doubtful. Hemolysins have been demonstrated to occur intermittently in the urine in pernicious anemia. The writer reports a case which showed occasional irritability, but, apart from the apathy, there was no more marked mental disturbance till a few hours before death. There occurred ten epileptiform attacks during the last of the illness, but on account of the high temperature shortly before death, the mental disturbance could not be called a pernicious anemia psychosis. Another case observed by the writer, complicated, however, by an organic brain lesion, committed suicide by cutting his throat and throwing himself from a window.

American Medicine, January 14, 1905.

The Foundations and Aims of Modern Pediatrics.—Theodore von Escherich (Vienna) traces the various steps which have developed pediatrics into a science. He divides child-life into (1) infantia, including, *a*, newborn period (first week of life), *b*, nursing period first year of life), *c*, milk teeth period (second to fifth year); (2) childhood (sixth year to puberty); (3) age of puberty. Under these heads he discusses the physiological principles involved in the growth of the child and the diseases incident to each period. He emphasizes the fact that the successful pediatrist must make himself familiar by special study with the therapy suitable to each period. He must bear in mind that a really curative effect can be obtained only from those measures which stimulate further or replace the naturally powerful healing processes of the childish organism. The greatest difference between the therapeutic problems of the pediatrist and those of the internist lies in the overwhelming importance and development of prophylaxis, which includes the constant and careful watching over the child's life (especially during the first period of growth). In closing his address the author calls attention to the value of children's hospitals and dispensaries which form the natural centers for practical education and scientific work.

Comparison of Roentgen Ray and Surgical Treatment of Tuberculosis.—James B. Bullitt concludes that surgery cannot make brilliant promises in the treatment of tuberculous affections. If successful, it is practically always dangerous, or tedious, one or both; and in the great majority of cases the patient fails of cure because of the exhaustion of his own or the surgeon's patience. On the other hand, reports of cases which have been made at length, seem to indicate that in some cases, at least, the tuberculous process can be cut short by exposure to the *x*-ray, and a cure effected in a much shorter time, and in the case of lesions of joints and bones, with much better functional results than is to be expected from usual surgical methods. It remains to show that the treatment is capable of causing arrest of the tuberculous process, and restoration to the normal condition. This must be done by careful observation and record of cases.

The Early Recognition of Hypertension.—Henry W. Cook directs attention to the importance of an early recognition of abnormal cardiovascular strain which is so frequently the precursor and direct causal agent in organic cardiovascular disease. Overexertion, either physical or mental, anxiety, overeating, especially of meats, and certain toxins produce a rise in blood pressure and therefore added strains on the cardiovascular system, upon the integrity of which health and life so directly depend. The routine use of accurate methods for estimating pulse tension in apparently trivial affections, will often be the means of detecting the existence of abnormal cardiovascular strain and of forestalling its later developments. When general hygienic and dietic methods fail to correct this condition specific treatment is possible by the vasodilators, the most generally useful being sodium nitrite in discs of .032 to .13 gms. (½ to 2 grains).

Lithemia: Its Diagnosis and Local Treatment.—F. M. Johnson emphasizes the satisfactory results obtainable from local treatment of lithemia in the shape of lavage of the kidneys and irrigation of the bladder. Many cases have responded much more quickly when this local treatment was used in conjunction with internal medication. For injection into the kidney, warm mild solutions of silver salts, or boracic acid are indicated. For washing out the bladder, mild formalin or silver nitrate, 1 to 5,000 in a half saturated solution of boracic acid appear to give the best results.

Journal of the American Medical Association, January 14, 1905.

Dairy Hygiene.—R. C. Newton considers this subject with special reference to the limitation of bovine tuberculosis. He notes that wild cattle are free from the disease and that the latter is curable and preventable in domesticated cattle as in man. Experienced dairymen estimate that 30 per cent. of all eastern cows are tuberculous, but these figures are uncertain. To eradicate the disease it is necessary not only to kill all diseased animals, but to institute proper sanitary measures among dairies. Not over fifty cows should live in one stable, and they should have regular exercise even in the coldest weather. The sun should shine in the stable all day long and the air space should be 1,200 cubic feet per cow. As to the value of the tuberculin test, the writer says that cows with advanced disease may fail to react, though the lesion is easily detected by physical examination. Even careful testing may fail to detect the disease or prevent its spread. On the whole, however, the test is reliable. The present laws against bovine tuberculosis are faulty. They reach merely the environment of the cause and not the cause itself. An owner may have his herd tested by a more or less competent veterinarian if he chooses, and may receive about one-half the value for the cattle that are condemned to be slaughtered, or he may, if he elects, remain in blissful ignorance of the real state of health prevalent in his herd and may maintain a hotbed of infection and disseminate tubercle bacilli among the unsuspecting populace indefinitely. We need also stricter laws against the sale of the carcasses of diseased cattle. Much of this meat is now sold to the bologna-sausage makers.

Paraurethritis.—J. W. Churchman reports two cases which illustrate the following points: (1) Gonorrheal infection of paraurethral ducts occurs in the male, and that it may manifect itself either during the course of an ordinary urethritis or before urethral symptoms have appeared. (2) Paraurethritis may, in its very early stages, simulate inflammatory lesions of the surface of the glands, notably beginning chancre, chancroid, or herpes. (3) Paraurethral infection, once it has become established, can be destroyed

only with great difficulty, the organisms reappearing in abundance even after cauterization of the duct. (4) The infection can be overcome without surgical intervention, and the continual existence of a neighboring focus of infection does not necessarily mean a bad urethral invasion if careful prophylactic measures are taken.

Berliner klinische Wochenschrift, December 26, 1904.

Syphilis as an Occupation Disease of Physicians.—Blaschko has had as patients no less than twelve physicians who have acquired syphilis in the course of their work, ten of the number coming from Berlin alone. In nearly all cases the primary lesion developed on the fingers, and three conditions must be differentiated from a chancre in this situation. These are herpes, anatomical tubercle, and chancroid, but they usually do not present diagnostic difficulties. In some cases, however, the chancre is extremely small, not painful, and heals without forming a scar, and in one case, not included in the above list, no site of external infection could be detected, which leads the author to believe that syphilis without a preliminary primary lesion is possible, and that the infection may perhaps occur through the bites of insects. The two chief sources of infection, are punctures with instruments during operations, especially on enlarged glands, and through unnoticed slight wounds, hangnails, etc., in major or minor gynecological practice. One case was directly traceable to infection in the course of an autopsy on a syphilitic cadaver. The author recommends that some moderation be used in the employment of the scrubbing brush in the process of sterilizing the hands, so as to avoid producing the many slight traumata usually found about the hands of those who operate frequently, and further that rubber gloves be used more extensively in operating and making examinations. If any wounds or fissures are discovered, they should be touched with a 2-3 per cent. solution of silver nitrate, covered with a piece of adhesive plaster; and the whole coated with collodion or covered with a finger cot. If infection is suspected, silver nitrate and bichloride are unsatisfactory, owing to their lack of penetrating power, and the author advises thorough washing with water, followed by the application of iodine and peroxide of hydrogen. The electrolytic needle and the actual cautery may also be employed. An infected physician need not give up his profession, but by observing stringent precautions, may continue to practise without any danger to his patients.

Munchener medizinische Wochenschrift, December 27, 1904.

The Treatment of Sciatica.—Lange describes a plan which he has found prompt in giving relief in intractable cases of sciatica. The method consists in injecting a considerable quantity of fluid into the nerve itself, and is carried out as follows: The solution used contains one part to 1,000 of eucain-β in 8 per cent. salt solution, and is sterilized by heat. The point of exit of the nerve from the sciatic foramen is located, and the superficial parts are anesthetized with the solution in a syringe provided with a long needle. The needle is then carried deeper into the tissues down to the nerve, which is situated at a depth of about 7 cm., and is not difficult to strike, as it is over a centimeter in width. The course of the needle through the skin and muscle is not painful, but as the nerve sheath is entered the patient gives a convulsive jerk. This indicates that the nerve has been reached, but the pain lasts only a moment, as the fluid is at once injected, 70-100 c.c. being forced in quite rapidly. The patient is told not to lie on the affected side for some time after the injection, and the feeling of tension produced usually disappears after a few hours. In some cases the injection must be repeated after several days. A rise in temperature was observed in some of the cases, but this promptly subsided. The author's cases are eleven in number, and in five the treatment was effectual, twice after a single injection, and three times after two injections. Another case was doubtful, four were improved, and one was not influenced. Although the number of cases is small, the dramatic nature of the prompt and complete cures obtained in bed-ridden patients whose sufferings had not yielded to any of the ordinary anodynes, leads the author to publish his results in the hope that others will make use of it in order to determine the type of cases amenable to the method, and the permanency of the cures thus effected.

Accidental Vaccination.—Lublinski considers it of importance to warn the persons in charge of the newly vaccinated, of the danger of accidental infection from the pustules. The greatest care and cleanliness must be observed, and precautions are necessary to prevent contact with other children. Patients with eczema or prurigo, are especially susceptible to generalized vaccina, and should never be vaccinated until cured, in spite of Unna's advice to vaccinate such children in the hope of effecting improvement in the eczema. Seven fatal cases in twenty-one of accidental infection, have been reported and show the predisposition to dangerous complications caused by eczema. The author recently observed a nasal infection in a woman who used her handkerchief in cleansing the vaccination pustule of her child, and then wiped her nose with it. The lesions produced were not severe and subsided spontaneously in the course of fourteen days.

Deutsche medizinische Wochenschrift, December 29, 1904.

The Radical Cure of Ventral and Umbilical Hernia.—Karewski has found that the following procedure gives good results even in extensive ventral and umbilical hernias. The scar is circumscribed by an incision sufficiently distant from its edges to be situated in healthy skin, and the mass of cicatricial tissue is dissected out, avoiding injury to the peritoneum if possible. If it is inadvertently nicked, the cut is at once sutured with fine cat-gut. The skin and subcutaneous tissues are stripped back on either side and the aponeurosis of the muscles surrounding the hernial ring is then incised completely around the circumference of the opening, and from 1-2 to 1 c.c. from its edge. This strip of tissue is inverted over the hernia, which is pushed back into the abdomen and the edges of the fascia sutured, thus forming a layer of tendon over the peritoneum. Deep sutures are then so placed as also to draw the muscles together over the gap, which can usually be done without difficulty. The author has treated thirteen cases by this method, with excellent results in all but one.

The Value of Oxygen Inhalation.—Aron does not attribute a great deal of value to the inhalation of oxygen in cases of carbonic acid intoxication, arising from any cause. Three methods of administration are in general use, direct inhalation from the cylinder of compressed gas, inhalation through a face piece or other reservoir provided with valves, and inhalation through a soft rubber mouthpiece. None of these can effect saturation of the blood with oxygen, though the latter method comes nearer to this end than any of the others, but it is inapplicable to very weak or dyspneic patients, owing to the degree of strength and attention needed to keep the lips tightly closed about the mouthpiece. The good results apparently due to the effects of oxygen inhalation depend on the increased depth and regularity of respiration accompanying its administration, and this is illustrated by a case coming under the author's observation. A little girl with deep cyanosis, due to a congenital heart lesion, showed prompt improvement in color on being allowed to inhale oxygen from a spirometer, but exactly the same result followed when air was substituted for the oxygen in the reservoir, and inhaled in a similar manner.

The American Journal of Medical Sciences, January, 1905.

Osteogenesis Imperfecta (So-called Fragilitas Ossium).—P. William Nathan declares that although this condition has been fairly well known to pathologists for some time, the cases reported have been practically all confined to stillborn or premature infants, and thus they have not been recognized or studied by the clinician up to the present time. He has not been able to find any case in the living subject, that has ever been reported under the name of osteogenesis imperfecta. He describes two cases that have come under his personal observation. In this disease the extremities are often much bent and deformed, and are always so brittle that the slightest violence results in fracture. The fragility of the bones is not confined to the extremities, but extends to all of the bones of the body. Ossification of the cranial vault is always defective. Sometimes this vault consists simply of a soft membranous sac. The bones are extremely porous. Calcification of the ostoid tissue is defective, and in some places absent entirely. Osteogenesis imperfecta is a systemic bone disease, which attacks the very young fetus. The first case mentioned by the writer is a male child and was 16 months of age when first seen by him. Although all of the fractures which this child has suffered are not remembered, at least twelve have been verified. The second case is a boy of 17 years. He has sustained no less than 35 fractures. All of his bones present a remarkable series of deformities. He has a circumscribed spinal lordosis in the lower dorsal region. His general health is good, and he is intelligent. So is the other patient whose case is reported. The cause and pathogenesis of this disease are as yet complete mysteries. The treatment consists in placing the patient in a position to avoid fracture. If the disease is mild, proper braces will be of benefit, by protecting the limbs.

Erythema Infectiosum.—Henry Larned Keith Shaw reports a separate exanthem, which has been recognized and classified by Escherich. It may be defined as a feebly contagious disease, occurring chiefly in children, with very slight subjective symptoms, and characterized by a maculopapular rose-red rash, more pronounced on the cheeks, legs, and outer surface of the arms. The specific agent is unknown. The disease occurs in epidemics, and often follows an outbreak of measles or rötheln. It is doubtless contagious. The age most subject to it is between four and twelve years. Both sexes are equally affected. It occurs

most often in the spring and summer months. Generally, the first symptom noticed is the eruption. A diagnostic feature of the disease is the character of the rash on the face. The cheeks are chiefly affected, and present a symmetrical rose-red efflorescence. The whole appearance is suggestive of erysipelas. On about the second day, the rash appears on the body. The appearance is often suggestive of lacework, especially when the rash begins to fade. It is not followed by desquamation. The lymphatic glands are not enlarged. There is no coryza or cough. The urine is normal. The prognosis is favorable. There is no involvement of the mucous membranes, and there are no constitutional symptoms. The disease has clinical features enough to justify its classification with the acute exanthemata.

Primary Sarcoma of the Bladder.—J. A. Wilder concludes that sarcoma of the bladder is most common after middle life, and during childhood, but it may occur at any age. It is more common in males than in females. The most constant symptom is hematuria. This cannot be considered an early sign, in many cases. Next to hematuria the most constant symptoms are those of cystitis and vesical irritation. Emaciation consecutive to the growth is present in advanced cases only. A calculus may or may not be present. In females the growth may invade the urethra, and appear at the vaginal opening. The disease is more rapidly fatal in children than in adults. In cases in which the diagnosis has been made early, the neoplasm has been small, single and apparently localized. The growth may spring from the submucosa of any part of the bladder, but the most common location is at the base, in the vicinity of the ureteral orifices. The growth is usually sessile with a broad base; soft and friable, more or less lobulated and in some cases it has a cauliflower appearance. Although usually single, it may be multiple in the later stages. Metastases, as compared with sarcoma of other parts of the body, seem rare except in quite advanced cases. Several varieties of sarcoma have been reported as occurring in the bladder. The only hope at present for the cure of sarcoma of the bladder seems to lie in the early detection of the neoplasm by means of the cystoscope or by exploratory incision, and its complete removal at this stage of the disease.

A Case of Spontaneous Arrest of Growth in an Endothelioma, with Subsequent Inflammatory Absorption.—B. M. Randolph reports this case. The patient was a Hebrew, 43 years of age. He has always been healthy. Three years ago there appeared on the posterior surface of the left forearm at about the junction of the upper and middle thirds, a small movable and painless nodule. The mass grew steadily for six months. From that time till two weeks before operation it remained stationary. It then began to be painful and to show signs of inflammatory reaction. The mass was excised, and the wound healed by primary union. There was no evidence of recurrence six months after operation. The writer then gives a detailed description of the microscopical appearance of the growth. He considers it an endotheliomatous growth which started in the subcutaneous connective tissue; it grew steadily for six months, and then for some unknown reason became arrested. A necrosis of the tumor cells then took place, and later this inactive tissue began to act as an irritant, and the response was a productive inflammatory process which endeavored to remove a foreign mass.

The Mental States Associated with Chorea.—A. W. Hoisholt after reviewing the classification of this disease, gives a description of two cases of dementia choreica. When walking, these patients show a striking resemblance in posture to the propulsion seen in cases of paralysis agitans. The large and small spasms are mixed in kaleidoscopic fashion, and there is a marked difference in their velocity. There is no rhythm about the spasms. The movements remind one of a jumping-jack. One of these cases here reported would appear to be of traumatic origin. In each case there is irritability, seclusiveness, history of persecutory ideas, characteristic speech defects, and progressively increasing dementia. As to the pathogenesis of chorea, the opinion has been recently expressed that the forms of chorea which are more or less of a chronic nature, such as Huntington's chorea, have many points in common with hysteria and epilepsy, and probably have a kindred pathology in the cortex.

The Effect of Suprarenal Preparations on Living Protoplasm.—Beaman Douglass has performed a series of experiments in order to determine the effect of suprarenal preparations on living protoplasm. The results of this work go to show that suprarenal preparations have a marked effect on cell division of healing tissue and upon the proliferation of cells constituting granulation tissue. It may be assumed that these solutions will have an effect depending upon the strength of the solution as well as the duration of the exposure, and that it is possible to kill cells or to prevent their activity, or retard cell division. The writer believes that the vitality of protoplasm is weakened by suprarenal solutions. As to the effect of these preparations on cilia, in solutions of 0.000003, there was an increase in the activity of the ciliate movement over the normal, in the eggs of the sea-urchins, while in other strength solutions there was a decrease. The turtle heart was used to determine the effect on contractile tissue. The experiments all showed that suprarenal solutions were powerful muscle stimulants. The writer believes that we are warranted in asserting that suprarenal preparation, at least in the lower animals studied, have a tremendous influence on the power of cell division, on the development of protoplasm, on the movement of cilia, and on contractile tissue.

The Influence of Suprarenal Extract Upon Absorption and Transudation.—S. J. Meltzer and John Auer give the following brief résumé of their results: (1) Intravenous injections of suprarenal extract retard invariably the processes of absorption and transudation. (2) Subcutaneous injections also often show a retardation of these processes; the effect, however, is neither strong nor constant. (3) In frogs the retardation of absorption of some substances was recognizable only when suprarenal extract was previously mixed with that substance, or when both substances were injected into one and the same lymph sac. (4) It is assumed that the suprarenal extract increases the tonicity of the protoplasm surrounding the pores of the endothelia of the capillaries, thereby reducing the facility for the interchange between the blood and the tissue fluid.

Some Practical Observations on Suppurative Hepatitis.—William W. Ashhurst says that the diagnosis of this condition is sometimes extremely easy, while at other times it must be made rather by exclusion. It probably often happens that suppuration in a small focus follows primary hepatitis. The great difficulty is to localize the focus. Sensitiveness to deep pressure is doubtless the most useful sign. Localized edema of the surface is also a sign of great importance, but it is rare except in very large or very superficially situated abscesses. Aspiration is best performed directly over where the focus is believed to exist. If a slender trocar is used there is no danger, but with the use of a thick trocar, which is sometimes necessary for the evacuation of thick pus, there is danger. After the diagnosis is made, the question of operation must be decided. The writer discusses this question with considerable detail, weighing the different methods and their indications. When it is necessary to resect ribs, he believes that it is better to use general anesthesia with ether or chloroform.

French and Italian Journals.

Popliteal Aneurysm; Extirpation; Recovery.—Arrou reports this case. The patient was a young man, an old syphilitic. The aneurysmal tumor was voluminous, extending upward the breadth of four fingers above the articular space; below, its limits were not clearly defined, as the ramifications penetrated the deep tissues and were lost under the muscles of the calf. Specific treatment met with no success, and as the patient suffered extreme pain, Arrou decided to extirpate the aneurysm. The operation was extremely difficult on account of the thinness of the walls, and because of the adhesion to the neighboring organs, especially the nerves. The lower ligature had to be placed two centimeters below the point of emergence of the anterior tibial. Recovery was uninterrupted. There was at no time any cause to fear that gangrene might develop.—*La Presse Médicale*, December 3, 1904.

"Angular" Pregnancy.—P. Puech describes a peculiar distortion of the uterus which sometimes occurs in the beginning of pregnancy, and which is of practical interest since it may give rise to errors in diagnosis, the consequences of which are sometimes grave. This abnormality consists in the enlargement of one of the cornua, and one border of the organ only. In this condition, the uterus has been compared to a face swollen from an inflamed tooth. On palpation it would seem that a tumor is annexed to the uterus. The enlarged portion of the uterus gives a different sensation to the hand than the part that is not hypertrophied. While the body of the organ preserves its habitual firmness, the cornu which is the seat of the hypertrophy, offers a great contrast by its flabbiness. Besides, this distended cornu enjoys a relative mobility, as if there existed between it and the rest of the uterus a zone in which the softening was especially marked. In such cases there is a groove of separation more or less distinct, between the hypertrophied horn and the rest of the uterus. Among 15 observations, four of them personal, this condition developed eight times on the left, and seven times on the right. The cause of this distortion has been variously interpreted. As a rule, angular pregnancy does not give rise to any special phenomenon, but goes on to terminate in a normal labor. The irregularity in the form of the uterus constitutes only a temporary phase which disappears with

the progress of gestation. It appears in the beginning of pregnancy, and is most clearly apparent in the second month. It is rare that it persists beyond the fourth month. Finally, the uterus develops as in a normal pregnancy, presenting a uniform distention and consistence. Sometimes this condition is accompanied by pain and bloody discharge. The possible errors in diagnosis are numerous. The condition is sometimes mistaken for uterine fibroma, tumors of the ovaries and tubes, inflammatory lesions of the adnexa, and extrauterine pregnancy. Although the diagnosis between this last condition and angular pregnancy is difficult in certain cases, it is, nevertheless, not always impossible. Differential diagnosis will depend especially upon the signs furnished by exploration of the tumor. Treatment of angular pregnancy does not call for any special consideration. If there is pain or bloody discharge, rest in bed and uterine sedatives are indicated. Absolute rest is also recommended when there is doubt concerning the diagnosis. The physician should, in these cases, beware of the danger of abortion. The writer is inclined to think that this condition is the cause of abortion in a certain number of cases which occur in the third and fourth months, which cannot otherwise be explained.—*Gazette des Hôpitaux Civils et Militaires,* December 1, 1904.

Bacteriology of Acute Vaginalitis.—Henri Hartmann, Ch. Esmonet, and P. Lecène in their recent studies of cases of this nature, have made examinations in 15 instances, with the following results: In seven cases of blennorhagic vaginalitis, they have in two cases found nothing; in one case, direct examination and cultures showed the presence of the gonococcus in pure state; once the secretion extracted from the infected parts, contained the streptococcus in short chains, once the staphylococcus albus, twice the streptococcus in short chains associated in one case with the staphylococcus albus, and in the other case with the staphylococcus aureus. In seven cases of vaginalitis of urethral origin, following catheterization, these investigators have found in the secretion from the vaginalis, once the colon bacillus, once the white staphylococcus, once the streptococcus in short chains, once the streptococcus in short chains, associated with the staphylococcus, once the streptococcus in long chains associated with the golden staphylococcus. With the exception of the last case, which suppurated, and had to be incised, all recovered spontaneously. Finally, in one case of vaginalitis in an old man, in whom the gland was extremely filthy, but who had not had gonorrhea, and who had not been catheterized, the white staphylococcus was found. The writers conclude that the secretion of vaginalitis is not only the result of an inflammatory reaction of the neighboring parts by extension from a lesion of the epididymus, but that it contains infectious agents whose pathogenic rôle is not to be questioned. They think that these facts are in favor of the lymphatic origin of epididymitis, and of treatment by puncture of vaginal effusions. The secretion from these cases was obtained by puncture, and under the most careful antiseptic precautions.—*Revue Française de Médecine et de Chirurgie,* December 5, 1904.

Carcinoma of the Breast Relieved by Radiotherapy.—Bergonié and Cassaët report this case. The patient was seen in May, 1902. She presented a cachectic aspect clearly due to carcinoma of the breast. As the patient was 72 years of age, and her general condition so bad, all surgical intervention was avoided. The administration of quinine and arsenic alternately met with no improvement, and the patient was subjected to the *x*-ray treatment for a year. This treatment had to be interrupted, but was later renewed. It was followed by improvement to a considerable extent in the condition of the ganglia, in the collateral circulation, and in the general condition.—*Journal de Médecine de Bordeaux,* December 4, 1904.

The Reaction of Human Blood Serum.—E. Tedeschi advances, as the best method of testing the reaction of blood serum, a method based on the osmotic theory of electromotive force, which in experiments on animals has given results on which confidence may be placed. As a result of the author's experiments, he recognizes two reactions of blood serum; an actual reaction, not alkaline, but neutral, and a potential reaction that is alkaline; for the vital processes a neutral medium is necessary, and nature maintains such a reaction normally, in health. In disease, the reactions may be altered, and especially so in diabetes mellitus, and in uremic coma, in which the reaction of the blood becomes nearly acid. In these conditions the blood becomes much reduced in strength, and hence the lack of resistance of the organism.—*Rivista Critica di Clinica Medica,* November 19, 1904.

The Laterovaginal Incision in Vaginal Hysterectomy.—Paolo Fiori advocates the method of Ruggi, who uses a laterovaginal incision, in hysterectomy for cancer of the cervix and body of the uterus, or in any condition where a large opening is necessary for extraction. The laterovaginal incision enlarges the vaginal opening, so as to permit of the easiest operation in cases of adhesions and of inflammatory and neoplastic enlargements of the uterus, as well as when the surrounding tissues are infiltrated, or there are extensive cervicovaginal cicatrices. The operation is done as follows: The operator grasps between the thumb and forefinger of the left hand, near the posterior angle of the vulva, the labia majora, and minora of the left side, and the corresponding portion of the vagina; the assistant does the same in front; the pressure renders the procedure bloodless. A deep incision is made, beginning at the point of union of the left lateral fornix, and includes all the lateral walls of the vagina, and the vulva, extends down into the ischiorectal space, and divides all the tissues of the anoperineal region up to the anal orifice. The author has used this method in a case of very large ulcerated epithelioma of the cervix with encouraging success.—*Il Policlinico,* November, 1904.

Experiments on the Negri Bodies as the Cause of Rabies.—A. Cardarelli has experimented by inoculation of rabbits, with material from rabid animals, making the inoculations into the nervous system. The inoculations were made by depositing on the cerebral cortex the virus from a rabid animal. He formulates the following conclusions: 1. If nerve matter from a rabid animal be deposited on the cerebral cortex, the virus remains localized on that spot for a great part of the period of incubation, and never leaves this location even when the infection becomes virulent in other parts of the nervous system. During the first few days the virus becomes attenuated. 2. If we deposit on the cerebral cortex of a rabbit, the cornu ammonis of an animal which is rich in the Negri bodies, these remain recognizable up to the fourth or fifth day, but take on no changes that indicate biological activity. On the other hand they appear necrotic, as do all the nerve tissues inoculated. Soon it becomes impossible to find the Negri bodies. In the leptomeningitis caused by the inoculated tissues, no Negri bodies can be found, even during the period of undoubted virulence. 3. Negri bodies in a pendant drop on a warm slide show no movement. After being in a collodion sac for some days in the abdomen of a rabbit, they still show no movement. 4. When used in the last-mentioned manner, after some days, they show no alterations that indicate life, but those that denote necrosis.—*La Riforma Medica,* November 9, 1904.

Varicose Veins in the Bladder in Reference to the Diagnosis and Treatment of Vesical Calculus.—N. Leotta details a rare case of varicose veins in the bladder, in which the varicosities were not limited to the most usual location, the neck and base, but were uniformly spread over the surface of the organ. There also existed a calculus, for the removal of which litholapaxy was done. The operation was followed after some hours by inability to micturate, and increase in the size of the bladder. On introduction of a large catheter, many coagula were removed, showing that serious hemorrhage had taken place into the bladder. The hemorrhage continued to be severe and necessitated suprapubic cystotomy. The patient died of a purulent pleurisy with uremic toxemia. The author's conclusions are as follows. (1) Varicose veins, generally limited to the neck and base of the bladder, may be spread over the entire surface. (2) In every operation on the bladder the possibility of fatal hemorrhage from varicose veins must be thought of. (3) Especially in cases of calculus must this lesion be considered in deciding on the kind of operation. (4) Cystoscopy should always be one of the preliminaries. (5) Varicose veins constitute a contraindication to litholapaxy, an artificial opening into the bladder becoming necessary. When hemorrhage has occurred, a cystotomy with tampon offers the best method of control.—*Il Policlinico.*

The Method of Partsch in Cysts of the Maxilla.—S. Ottaviano calls attention to the value of the method of Partsch in the treatment of cysts of the maxilla, when occupying a large portion of the maxilla, so that removal of the diseased bone would produce great disfigurement and loss of function. The method consists in opening the cyst freely, attaching the mucous membrane of the mouth to the edge of the cyst lining, and allowing the cyst to become a cavity opening freely into the mouth. Cysts of the maxilla may be of three kinds: (1) Radicular cysts, or periosteal cysts, attached to the root of a tooth; (2) Follicular cysts, formed by a dilatation of a tooth sac; (3) Multilocular cystoma. The author details a case in which there were two cysts, one of the maxillary arch of the lower jaw, the other in the ramus of the same side. The anterior cyst had occasioned the gradual loosening and removal of nearly all the teeth of that side, and had been opened freely and allowed to become part of the mouth cavity. The second cyst was treated in the same manner, with the best of results, the operation being quite simple, and the patient finding no bad effects from the enlargement of the mouth cavity.—*La Riforma Medica.*

Book Reviews.

Travaux de Chirurgie Anatomo-Clinique. Par Henri Hartmann, Professeur Agrégé à la Faculté, avec la Collaboration de B. Cunéo, Lecène, Lebreton Esmonet, Lavenant et Prat. Deuxieme Série, Voies Urinaires, Testicule. Avec 105 figures. Paris: G. Steinheil, 1904.

Last year we were pleased to review the first series of these hospital statistics and laboratory investigations, so carefully worked out and worked up for presentation, embellished with noteworthy pathological drawings. The study of experimental tuberculosis of the testicle, the histology of blennorrhagic epididymitis, primary epithelioma of the male urethra, and many other subjects are presented in an interesting manner.

First Report of the Welcome Research Laboratories of the Gordon Memorial College, Khartoum. By the Director, Andrew Balfour, M.D., B.Sc., M.R.C.P., Edinb., D.P.H., Cambr., etc. Khartoum: Department of Education, Sudan Government, 1904.

After some pages, given to a description and illustration of the laboratories, the bulk of this publication is devoted to the mosquito work in Khartoum and the Anglo-Egyptian Sudan generally. The work reported seems to have been thorough. Besides the mosquito work, this report contains articles on biting insects other than mosquitos, and one describing and illustrating the species of mosquitos of Egypt, the Sudan, and Abyssinia. Throughout the work is well illustrated, colored plates being numerous.

Syphilis and Gonorrhea. By C. F. Marshall, M.D., Ch.B., B.Sc., Vict. F.R.C.S., Eng. Senior Assistant Surgeon to the Hospital for Diseases of the Skin, Blackfriars, London. London and New York: Rebman Company, 1904.

The author gives in this 260-page book his criticisms and conclusions upon the chief points in syphilis and gonorrhea which he has found in consulting the authorities of England and France.

The print is large, the headings larger, the paper light, so that all has been done by the printer to make the book readable. The author, too, has left out wordy padding and what is retained has reason for so being. The pages abound in quotations and an appendix contains "further references," but none later than 1900.

Multiple Personality: An Experimental Investigation into the Nature of Human Individuality. By Boris Sidis, A.M., Ph.D. (Harvard), and Simon P. Goodhart, Ph.B. (Yale), M.D. New York: D. Appleton & Co., 1905.

This work is an examination into the biologico-psychological problems connected with the conception of personality. The first part deals with the biological question, "what is an individual?", the biopsychology of animal colonies, and the progressive integration of personality during the long evolution of the human race. The second part (pp. 83-202) is devoted to a thorough detailing of the Hanna case, which is the first case of complete amnesia and double consciousness which has been under direct personal observation as well as under experimental control. The case is that of a clergyman, who, following an accident, lost all recollection of his past life and had to learn again everything from the beginning; and who was later on enabled to merge the two personalities (the natural and later recollected one, and the later one developed through re-education after the accident) into one. The third part is devoted to a discussion of the problems of consciousness and multiple personality. The second part is by both authors; the first and third by the senior author alone. Altogether, the work offers an interesting presentation of fact and theory in this obscure department of psychology.

Beiträge zur wissenschaftlichen Medicin und Chemie. Festschrift zu Ehren des sechszigsten Geburtstages von Ernst Salkowski. Berlin: August Hirschwald, 1904.

This Festschrift, in honor of the sixtieth birthday of Ernst Salkowski, is one of the richest in material among the recent publications of its kind. Beginning with an article on the Charcot-Leyden Crystals by v. Leyden himself, the volume presents an array of papers on a variety of subjects which vividly illustrates the convergence of nearly all branches of medicine in physiological chemistry—the science of which Salkowski is probably the foremost exponent today.

The American contributions include three articles: One by A. E. Austin, of Tufts College, Boston, on the Union of Indol and Phenol with Sulphuric and Glycuronic Acids in the Urine; one by Max Einhorn and Robert Huebner, of New York, on a Colorimetric Method of Estimating Indol in the Fæces and the Urine by Means of Ehrlich's Dimethylamidobenzol Reaction, and one by W. R. Orndorff and J. E. Teeple, of Cornell University, Ithaca, N. Y., on Bilirubin, the Red Coloring Matter of the Bile. The only contribution from England is that of E. P. Cathcart, of the Lister Institute, London, on Urotryptic Digestion.

Out of the total of forty-six articles which constitute this volume, there are, in addition to the four from England and America just mentioned, one from Vienna, one from Warsaw, one from St. Petersburg, one from Rio de Janeiro, two from Tokio, and one from Padua. The contributions from Berlin alone number twenty-three, and the remaining articles come from the various smaller cities of Germany. In addition to two lithographic plates and other pictures, illustrating the text of the several contributions, there is a portrait of Salkowski.

Physiological Economy in Nutrition, with Special Reference to the Minimal Proteid Requirements of the Healthy Man. An Experimental Study. By Russell H. Chittenden, PhD., LL.D., ScD., Director of the Sheffield Scientific School of Yale University and Professor of Physiological Chemistry; Member of the National Academy of Sciences, etc. New York: Frederick A. Stokes & Company, 1904.

The four hundred and seventy-eight pages of this book contain the record of what is undoubtedly one of the most important contributions to the physiology of nutrition that has been made in many years. Actuated by a desire to throw light on the broad question of a possible physiological economy of nutrition, Dr. Chittenden planned and carried out a series of metabolism experiments on a large scale to determine the effects of a diminished proteid dietary when persisted in for months. Three classes of subjects were used. 1. A group of five professional men of varying ages connected with Yale University as professors and instructors. 2. A detail of thirteen men, volunteers from the Hospital Corps of the United States Army. 3. A group of eight young men, students in the university in constant training as athletes. The nitrogen intake and output of these subjects was determined and they were kept on a diet greatly restricted in its nitrogenous constituents, though by no means a vegetarian regimen. For details of the experiments, which were continued over many months, the voluminous tables of the original must be consulted, but in general it may be said that all three of these classes of men were able to subsist with comfort, and without any corresponding increase of carbohydrates or fats, on a diet containing less than one-half of the 118 grams of albuminous food which Voit considers a daily necessity for an adult man of average body weight. The bodily and mental faculties appeared to improve during the period of observation and the author says that once the habit of this restricted diet has been acquired one is slow to return to the former more liberal regimen. The economic as well as the scientific bearings of these results are most far reaching and the value of work done with such painstaking attention to detail cannot be overestimated.

A. L. A. Catalog. Eight Thousand Volumes for a Popular Library, with Notes. 1904. Prepared by the New York State Library and the Library of Congress Under the Auspices of the American Library Association Publishing Board. Editor, Melvil Dewey, Director, New York State Library and Library School. Associate Editors, May Seymour, Education Librarian, New York State Library; Mrs. H. L. Elmendorf, Special Bibliographer, Buffalo Public Library. Part 1, Classed. Part 2, Dictionary. Washington: Government Printing Office, October, 1904.

This is a volume the value of which can hardly be overestimated, while it represents an amount of work that beggars calculation. Its ostensible purpose is to furnish for the use of public and private libraries a catalogue of the 8,000 volumes deemed most suitable for the general reader, but it has a much wider range of usefulness than this. The first lists were made out by a committee of two hundred and fifty collaborators, authorities in their various departments, and from these the editors selected the books that appeared to them to be most suitable. The list is arranged in two forms, one based on the Dewey decimal system, which is no doubt the most important of the many contributions its deviser has made to the subject of library lore, and the other an alphabetical dictionary catalogue. A more or less critical résumé of each volume is given, together with its price, publisher, etc. Therefore, in addition to its value for its more technical use in libraries, the volume affords a most satisfactory universal bibliography for any reader, and although, as is natural, the lion's share of the total number of volumes is devoted to literature and history, the other branches of knowledge are well represented and contain lists of great service. Libraries may receive one copy of the work free of charge, and copies may also be obtained by addressing the Superintendent of Documents, Washington, D. C., at the nominal charge of fifty cents, in cloth binding, and twenty-five cents, in paper.

Therapeutic Hints.

Tinea Tonsurans in Children.—Cut the hair as close as possible once a week. Every two days wash the head with soap and warm water. Morning and evening massage the scalp, triturating the diseased spots energetically. After the massage, prolonged friction by means of a tooth-brush with the following liniment:—

℞ Spirit. camphor ..... ℥iv
Castor oil ..... ℥j
Tincture of cantharides ..... ℥j
—*Medical Press.*

Pharyngitis —

℞ Potassii chloratis ..... gr. xij
Glycerini ..... ℥j
Aquam ..... ad ℥i
M.

℞ Acidi carbolici liquefacti ..... m iij
Glycerini ..... ℥j
Aquam ..... ℥i
M. —*Medical Times and Hospital Gazette.*

Pruritus.—

℞ Acid. salicyl.
Acid. carbol.
Naphthol. ..... āā 0.5
Lanolin
Petrolati ..... āā 30.0
Acid. acetici
Aquæ ..... āā 15.0
M. et ft. ungt.
—*Wiener Klinische-Therapeutische Wochenschrift.*

Impacted Cerumen.—

℞ Sodii bicarb. ..... gr. xx
Glycerin ..... ℥j
Aquæ dest. ..... ℥i
M. —*Medical Digest.*

Insect Bites.—First apply aromatic spirit of ammonia to neutralize the poison, and then apply:

℞ Liq. plumbi subacetat ..... ℥ss
Tinct. opii ..... ℥ss
Aquæ destillat. q. s. ad ..... ℥viii
M. Sig. Apply soft gauze saturated with solution to inflamed area. —*Medical Digest.*

Hemoptysis.—The best treatment of hemoptysis requires: (1) absolute physical rest; (2) mental quiet and relief from fear and anxiety; (3) morphine and atropine to supplement dosage to insure both the preceding; (4) control of cough, fever, and pleuritic pain and careful attention to diet; (5) suggestive measures as ice caps over the heart, salt and cracked ice by mouth, etc.; (6) free use of bromides and nerve sedatives in the nervous; (7) nitrites or veratrum when high blood-pressure persists; (8) care in not overdrugging or in placing reliance on specifics as ergot or adrenalin; (9) hypodermoclysis with normal saline when indicated.—FITZGERALD in *Cleveland Medical Journal.*

Chronic Eczema.—

℞ Sulphuris præcip. 10.0
Spir. vini 30.0
Glyc. 5.0
M. Sig. Shake well and paint on the affected parts.

℞ Sulphur. præcip. 20.0
Sap. virid. 5.0
Ol. cad. 10.0
Ungt. zinci 65.0
M. et ft. ungt.

℞ Chrysarobini
Acid. salicyl. ..... aa 15.0
Sulph. præcip
Sap. virid.
Ol. cad. ..... āā 20.0
Lanolini 100
M. et ft. ungt.—*Wiener klinisch-therapeutische Wochenschrift.*

Chancre.—

℞ Vaselini 15.0
Lanolin 5.0
Resorcin. 0.5
White precipitate 1.0
La Presse Medicale.

Pruritus Vulvæ.—

℞ Acid. carbolici ..... ℥j
Acid. salicylici ..... ℥i
Morphin. muriat. ..... gr. i
Vaselini ..... ℥j
M. et ft. unguent. Sig. Apply several times daily.
—*Buffalo Medical Journal.*

Pneumonia.—The most useful *single agent* in treatment as prophylactic and curative remedy, used practically in inhalations, properly given and continued for a sufficient length of time.—BEVERLEY ROBINSON in *American Journal of the Medical Sciences.*

Inflammations of Mucous Membranes.—Formaldehyde when mixed with four per cent. of glycerin makes an admirable local application in diphtheria, tonsillitis, rhinitis, stomatitis, vaginal and vulvar ulcers, tuberculous ulcers, etc., and causes only slight irritation and pain when thus employed.—*The Southern Clinic.*

Diarrhea.—Dr. J. J. Taylor's formula.

℞ Subnitrate of bismuth ..... ℥ss
Pulverized nutmegs
Prepared chalk ..... āā ℥ii
Sulphocarbolate of zinc ..... gr. xii
Syrup of ginger ..... ℥iii
M. Sig. Shake well. One teaspoonful after each passage. —*Texas Courier Record.*

Chronic Rheumatism.—

℞ Potass. iodidi ..... ℥i
Sodii salicylatis ..... ℥ii
Colchicin
Strych. sulphatis ..... āā gr. ss.
M. ft. caps. No. 30. Sig. One capsule to i. d.

In connection with the above a teaspoonful of the following powder should be administered in warm water every morning before breakfast:

℞ Sodii benzoatis.
Sodii phosph. ..... āā ℥i
M. —*Clinical Review.*

Alcohol Habit.—C. Carter has employed with success hypodermic injections three or four times a day of small doses (less than 1-100 gr.) of atropine. It produces, he says, a great distaste for alcoholic liquors in from one to five days.—*Denver Medical Times.*

Bronchopneumonia.—

℞ Vin. ipecac. ..... ℿ—v-x
Spirit ammon. aromat. ..... ℿ—v
Syr. tolu ..... ℿ—v
Aq. ad ..... ℥ii

To be given every four hours.—STANLEY in *Birmingham Medical Review.*

Intestinal Fermentation.—Dr. Friedrich Grosse gives the following as his favorite prescription for this condition:

℞ Bismuthi salicylatis.
Benzonaphthol.
Sodii benzoatis ..... āā gr. xlv–lx
Syrupi simplici ..... ℥ss
Aquæ q. s. ad. ..... ℥iv
M. Sig. One teaspoonful every three to four hours.—*Medical Review of Reviews.*

Society Reports.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 5, 1905.

THE PRESIDENT, DR. ANDREW H. SMITH, IN THE CHAIR.

Presentation of Annual Reports.—The treasurer reported that for the year ending December 15, 1904, the total receipts were $19,904.83; the total expenditures, $18,964.42; balance, $940.41. Dues outstanding, $1,358.

The Treasurer for the Board of Trustees reported that the total receipts for the year ending December 15, 1904, were $12,885.41; total expenditures, $8,788.81; balance, $4,096.60.

The Corresponding Secretary reported that the number of Resident Fellows elected during the year was 146; of Associate Fellows, 23; of Honorary Fellows, 33.

The Edward N. Gibbs Memorial Prize for the best original essay on the etiology, pathology, and treatment of diseases of the kidney was not awarded.

Address of the Retiring President. President Garfield at Elberon.—Dr. ANDREW H. SMITH, the Retiring President, made this the subject of his address. After a graphic description of the fatal illness of President James A. Garfield, who was wounded at Washington on July 2, 1881, and died at Elberon, N. J., during the following September, Dr. Smith gave an interesting account of the findings at the autopsy, at which he was present. He stated it was the opinion of all who had been in attendance on the case that the bullet had coursed downward on the right side of the body, and would be found in the right inguinal region. So confident were they of this theory, that it was agreed to remove the hollow viscera at once, as preliminary to a study of the track of the ball. This was done, and the organs so removed were received in a large receptacle and placed

in another part of the room. It was then found that the supposed fistulous track that was to have led to the bullet had no existence, for the flexible catheter which had been introduced into the wound in the usual manner as the first step in the examination was found curled upon itself and lying a pocket of considerable size which had formed beneath the iliac fascia. Deprived of the guide which this catheter was expected to furnish, the examination was continued in an aimless way through the neighboring muscles, the perplexity increasing every moment as to where the bullet could possibly be hidden. Attention was now directed to the point where the missile had entered the body, and it was then noticed that the bodies of several of the vertebræ were overlaid by a dense mass of partly organized exudate of almost cartilaginous consistency. When this was cut away, a hole was revealed in the right side of the body of the first lumbar vertebræ; into this a probe was passed in an oblique direction through the bone, emerging on the left side of the spinal column. Seeing this, Dr. Smith divined that the bullet must be in the left side of the body instead of the right, and crossing the room to where the detached viscera were, he began to pass them through his fingers and in a few moments came upon the bullet. Further examination showed that after passing through the vertebræ, in a direction slightly downward and backward, and keeping behind the peritoneum, it had lodged at a point just below the level of the left extremity of the pancreas (about ten inches from the location it was supposed to occupy), where it had become encysted. In its passage it had grazed the splenic artery, giving rise to a traumatic aneurism, the rupture of which was the immediate cause of death. The bullet, encysted as it was, was practically harmless, but in traversing the cancellous structure of the body of the vertebræ it had carried numerous fragments of bone before it, and these were strewn through the soft parts along the entire track, a distance of several inches. Each of these fragments became a center of suppuration and septic infection, a condition from which recovery was obviously impossible. From this, Dr. Smith said, it would be seen that the wound from the first was necessarily fatal. Another condition, equally hopeless, was that the thoracic duct was included in and compressed by the hard mass that enveloped the front of the vertebral column at the point of injury. The result of the autopsy showed clearly that no treatment whatever could possibly have saved the President's life. The track of the bullet was so devious that no instrument could be made to follow it, and at the point where it finally lodged there was no evidence during life of the presence of a foreign body. To open the abdomen, therefore, in search of the bullet would have been an unthinkable procedure. Furthermore, no practicable operation could have sealed up the wound through the vertebræ and rendered it aseptic, nor would it have revealed the injury to the vessel that later caused it to give way. Finally, the compression and obliteration of the lower portion of the thoracic duct could not have been prevented. This doomed the victim to gradual death by starvation. Antisepsis was carried out as perfectly as circumstances and the knowledge of the period admitted of, but in no case could it have been applied effectively through the whole course of the wound.

Address of the Incoming President.—By Dr. CHARLES L. DANA. In this address, the speaker said it was his aim to show that the medical profession, in view of an increasing prolificness of its work in the matter of articles written and read, and in view of the increased number of medical societies, and the demands put upon busy men, must take some measures for its self-protection, and these consisted in abolishing some of the modes of procedure which had been utilized in the past, and had descended to us by tradition. Next, that the medical profession must learn that unless it wished to be swamped by the exuberance of its own fertility, it should master the art of presenting what it desired to record with accuracy, clearness, and dispatch. In order to ascertain, if possible, the proportionate interest which medical men in general felt towards the different branches of medicine, Dr. Dana said he took three of the prominent medical weeklies in New York City, and the *British Medical Journal* of London, and went over all the original articles published in them during the year, 1903. There were about one thousand original articles in all. Out of 663 published in this city, a quarter of them were devoted to subjects of internal medicine, and a little less than one-quarter to general surgical subjects, including orthopedic and rectal surgery. Neurology and psychiatry came next, with 8 per cent.; genito-urinary surgery, 6 per cent.; obstetrics and gynecology, 6 per cent.; pathology and bacteriology, 5 per cent.; physiology and physiological chemistry, 3 per cent.; laryngology, 5 per cent; ophthalmology, 5 per cent.; hygiene, climate, tropical diseases, and preventive medicine, about 6 per cent.; radiotherapy, 6 per cent.; otology, 2 per cent.; government, railway, and insurance service, 1 per cent. In Great Britain the results were nearly the same, with two or three important exceptions. General surgery ranked in Great Britain considerably higher than internal medicine, in the proportion of 100 to 80. Pathology, bacteriology, and general laboratory research seemed to excite almost twice as much interest there as they did in New York, 10 per cent. of the articles in the *British Medical Journal* for 1903 being devoted to those subjects. Physiology and physiological chemistry were also very much more in evidence in Great Britain than here, in the proportion of about 4 per cent. for us to 7 per cent. for Great Britain. Naturally, the subjects of hygiene, climate, and tropical diseases also took a very much higher rank with the English.

Dr. Dana said it might be well for the Academy of Medicine to consider the wisdom of having the Council empowered to appoint a permanent committee on Public Health and Medical Economics. This committee should be a large one, and contain the best experts in sanitation, chemistry, pathology, and bacteriology, as well as men practically familiar with sanitary and educational administration. The policy of having special sections of the Academy had been justified by the splendid and successful work of those organizations, and by the increase in medical activity they had brought about. It seemed wise to have just as many sections as the Fellows would support without too much urging. If it was considered unwise to expand numerically in that direction, there was a possibility of combining some of the sections already established, provided this seemed entirely welcome to the members. Neurology and psychiatry had recently attracted increased attention, and these branches would be of larger importance still, if to them were added what used to be called forensic medicine. More interest, the speaker thought, might also be taken in the problems of pathology, physiology, and physiological chemistry, or the laboratory sciences as they were sometimes called. There were probably at present no problems in medicine so intricate, so fascinating, and so fundamentally important as these. To a certain extent it might be said that purely clinical medicine was worked out, for what more could be observed of the common phenomena of the every-day diseases? They appeared, it was true, in ever-varying phases and combinations, and each particular case had features of its own, but to make radical progress we had to go deeper and deeper into the biology of disease. The problems of metabolism, of immunity, of toxins, bacteria, ferments, and internal secretions, and the finer chemical changes were those which promised to enlighten and help us most richly in the future. Internal medicine, with the laboratory sciences as its handmaid, was rising to its former dignity and to the great prominence it deserved.

The Canada Medical Record, published monthly in Montreal, ceased publication with the number for April, 1904, just issued. The journal was established in 1872 and has been under the continuous editorial management of Dr. F. Wayland Campbell, a veteran medical journalist of the Dominion.

NEW YORK ACADEMY OF MEDICINE.

Section on Medicine.

Stated Meeting, Held December 20, 1904.

Dr. Charles H. Lewis in the Chair.

A Case of Pneumothorax.—Dr. George Mannheimer presented a man, 37 years old, with a right-sided pneumothorax of four months' duration. At no time had there been any fluid within the pleural cavity. He had sudden pain, severe dyspnea, followed by all the classical signs of pneumothorax, probably of tuberculous origin. The *x*-ray picture showed the presence of air in the pleural cavity, with a displacement of the diaphragm downwards. No needle at any time had been introduced into the chest, and the doctor was not certain as to the variety of pneumothorax he had to deal with. There was also gastroptosis, and the typical chicken breast. Pneumothorax without some effusion was a very rare condition, and Dr. Mannheimer asked the members of the section what should be done for the patient in the way of treatment. No tubercle bacilli had been found in the sputum.

Dr. Charles H. Lewis referred to a case that he had seen in the hospital where the dyspnea was more marked than in the case presented. It was in all probability caused by the bursting of a tuberculous focus into the pleural cavity during a severe attack of coughing.

Dr. Nathaniel Bowditch Potter advised non-interference.

Dr. Charles H. Lewis believed that the patient's best interest would be in letting it alone, and recalled a case seen a short time ago in which there was very severe dyspnea; aspiration was performed without any apparent benefit. This was in a case of acute phthisis, and the patient died three weeks later.

A Case of Acromegaly.—Dr. Mannheimer presented this patient, the wife of the man with pneumothorax, whom he had seen this morning for the first time. During the past three years she had required larger gloves and larger shoes. She presented all the characteristic symptoms and signs of acromegaly, not only of the bones, but also of the soft parts. Her eyes had not yet been examined. The abdomen was quite pendulous. She menstruated every three weeks, and the discharge was quite profuse. The increase in thickness of the parts was more marked than the increase in length. Her mental condition was fairly good.

The Employment of the Blind in Massage.—Dr. Nathaniel Bowditch Potter presented this communication, which was, in brief, a plea for the education of the blind in massage, and their employment in public places, such as hospitals, clinics, etc., and he hoped that some scheme could be organized by which they could obtain steady employment and be made self-supporting. Dr. Potter, three years ago, applied to the institutions for the blind, hoping to find material to teach massage, but he had not been able to find one who was willing to learn. A very careful selection should be made of candidates, and only by their teachers in the blind asylums. It was very essential that they should have a thorough fundamental training.

The Continuous Current in Relation to Inflammatory Exudates.—Dr. Margaret A. Cleaves read this paper. She referred to the present tendency to ignore the continuous current, a knowledge of which was fundamental to the study of the physical phenomena of electricity, as well as its therapeutical uses. The intimate pathology of inflammation and inflammatory exudate was the same, no matter what organ or tissue was implicated; it varied only with the anatomical site and structure and the physiological function. The inflammatory process might occur during the progress of a typhoid fever, more rarely these days of a puerperal fever, it might follow an operation for appendicitis, or a uterine curettage, and in each and every instance it was the venous circulation which suffered. When the process went on to the formation of connective-tissue bands the case was still further complicated. The inflammatory action might have been of a septic or rheumatic nature involving a joint. The acute lesion might have been recovered from, but diminished mobility resulted and the patient suffered discomfort and disability. Through the pressure and interference with the circulation congestive and low-grade inflammatory conditions were perpetuated, and the patient became the victim of chronic aches and pains, variously diagnosed as neuralgia, lumbago, rheumatism, etc. Every means should be exhausted as nearly as possible to restore every organ or part to its normal condition. If possible, inflammatory processes should not be permitted to go to the extent of organized exudate, when absorption became a much more difficult thing, while gland, neurons, and muscle-fiber had suffered beyond repair. The writer believed that classical medicine could secure to itself better results in this class of cases if it not only appreciated what could be done in the earlier stages of the pathological change, but knew what form of electricity to use, and how to use it.

It did not matter what organ or tissue was affected, so long as it was possible to apply electrode contacts so as to expend the chemicophysical energy of the continuous current directly within the mass of organized exudate. The less fully organization had taken place, the quicker and better the result. If it had gone on to the formation of connective tissue bands, little could be done beyond the improvement of circulatory conditions, softening the morbid tissues, and putting them in better condition for manipulation by the skilled masseur, or for the action of an alternating current. The different results obtained in the treatment of urethral stricture by electrolysis could, without question, be accounted for by imperfect differential diagnosis. Just so surely as the urethral, cervical, lacrymal, or Eustachian canal was narrowed by pressure of more or less well-organized inflammatory exudate, just so surely might it be relieved by the use of the continuous current. But if there were fibrous bands limiting the urethral canal, electrolysis must be accompanied by divulsion or cutting. Dr. Cleaves cited a series of cases of phlebitis from different causes, but presenting the classical picture, in which all other treatment had failed, and all of which yielded, save one, to the application of the continuous current. Treatment was continued in the entire series of cases from a few weeks to three and one-half months, and the improvement in every case, save the one referred to, was maintained, being characterized by a normal circulation, elasticity of the walls of the veins, disappearance of the inflammatory exudates, and diminution in size of the affected member. The continuous current was used in all of the cases, the greatest care being taken not to break the contact at any time during the treatment, in order to avoid sudden contraction of the muscles. It was not only necessary to select a current capable of producing chemical changes, electrolytic and cataphoric, stimulating the circulation and increasing the activity of absorbents, but at the same time a current that could be used so as not to cause any sudden muscular contractions, as such contractions might cause thrombi which were present to be released and get adrift into the circulation. At the end of three months these patients reported that they had 90 per cent. better use of their legs than when treatment was instituted, and they were able to indulge in outdoor sports. The writer cited other cases illustrative of the conditions which were benefited by the use of this form of electrical energy. She said that ordinary traumatic and rheumatic cases yielded much more promptly and completely than those in which sepsis had been a factor. The latter, if taken before there was any organization of the exudate, seemed to do well under the chemical energy of light.

Dr. A. D. Rockwell said that the whole question resolved itself into one of nutrition, for whatever influenced nutrition influenced all organic processes, because they were all connected with the nutritive power of the organism. It was demonstrable that the passage of electricity was of a four-fold nature, mechanical, physical, physiologi-

cal, and chemical, and nutritive effects were the result of their combined activity. With the use of the galvanic (continuous) current, he said, one got the chemical effect, and this influenced absorption, giving the body the power to absorb exudations, deposits, or morbid growths, and much more powerfully than could all the other forms of electricity combined. For many years he had been connected with a woman's hospital, and had been given the opportunity of seeing what could be done by the form of treatment described, especially in exudative conditions. Dr. Rockwell said he believed he was one of the first to call attention to the influence of the galvanic current in causing absorption of exudates in the pelvic region.

A Case of Chylous Ascites.—Drs. J. Finley Bell and S. P. Beebe presented this communication. Dr. Bell read the paper, and reported the case of a man whom he had seen on October 1, 1904. The patient was a German, 57 years old, a cabinet maker, who complained of dyspnea and certain swellings, especially of the pendant portions of the body. For several months previous he had attacks which were supposed to be malarial, characterized by chilliness and fever, for which he was given Warburg's tincture. Three years ago he was passed by an insurance company. The interesting features in the history were the sudden distention of the abdomen, the marked dyspnea, and cardiac failure. The blood examination, on October 1, showed 2,895,750 erythrocytes and 12,960 leucocytes, and a tentative diagnosis of hepatic cirrhosis was made. Paracentensis abdominis was done fourteen times between October 1 and December 17, withdrawing a total quantity of 106,370 c.c. of chylous fluid; the lowest amount withdrawn was on October 1 (4,000 c.c.) and the highest on December 7 (10,250 c.c.). A specimen of the fluid was shown. Its specific gravity was 1.011; it contained 2.5 per cent. solids; 2.75 per cent. proteids by the gravimetric method; of albumin, fibrin, and indican a trace. Microscopically, many fat globules, small and mononuclear leucocytes, and a large amount of granular material were found. One of the remarkable features regarding the case was so much loss of chyle with loss of only five pounds in weight. He had failed to find filariæ after many attempts.

Dr. S. P. Beebe said that few analyses of human chyle had been made. In some instances small quantities had been obtained from the thoracic duct, but could not be considered normal, because of the diseased condition of the patients. The milky character of the fluid, he said, might be due to other substances than fat, such as cholesterin. He could not state positively that the fluid obtained from this patient was pure chyle. It certainly had not the character of inflammatory exudates. He considered it chyle modified with an admixture of other material. The emulsion formed by it was a permanent one. Fat formed 61 per cent. of the fluid, and had a melting point of 34°. Its acid number was 9.4, showing more fatty acid was present than normally. The fat that resulted from fatty degeneration had a higher acid number than normal fat. He said this patient presented a great opportunity for determining the extent of absorption. For instance, the patient was given the glycerophosphate of iron, and none was obtained from the chylous fluid; the same patient was then given the tincture of the chloride of iron, and 100 per cent. of it was obtained.

Dr. Lewis A. Conner thought that the amount of fat was low, comparing it with what was found in true chylous ascites. He referred to Senator's statement that the absence of sugar was a pretty certain indication that the fluid was not chylous.

Dr. Robert T. Morris said that one might make a diagnosis of the character of the lesion by the character of the fluid. If the fluid was nearly all chyle, then one might assume that there was a ruptured chylous cyst or even a rupture of a larger vessel. He referred to a boy about 14 years old, who was tapped for an ascites of unknown origin. Examination of the fluid made him believe it was chyle, and the abdomen was opened to find the seat of obstruction; but none was found. The peritoneum was quite succulent. Because of a tuberculous history, he thought that possibly the obstruction was due to a tuberculous process in the peritoneum. After the operation there was some further accumulation of fluid, but not much; there was not sufficient distention to demand tapping again. The amount of fluid removed at the first operation was about 10 or 12 pounds. The good results were probably brought about by inducing a hyperleucocytosis, and a destruction of the tubercle bacilli. In these cases the patients might remain in the best physical condition because chyle was still in circulation, the peritoneum being a lymph chamber. Dr. Morris offered one theoretical therapeutic point; why could not something be introduced into the circulation which would cause an endosmosis towards the blood-vessels? If glucose could be given in large enough quantities it would attract the fluids toward the vascular system. In cases of sudden onset of symptoms pointing to a rupture of a chylous cyst or large vessel, Dr. Morris did not think it would be a bad idea to open the abdomen and look for the rupture.

Dr. Bell said that it was true an absolute diagnosis had not been made. It might be a tumor involving the thoracic duct. But it did not explain why the patient refused to waste, when he was not getting the full amount of chyle; he was getting about one-third or one-fourth of all that he was manufacturing. Attempts to map out some neoplasm in the abdomen had failed. His personal belief was that he had a chylous cyst which ruptured, discharging its contents into the abdominal cavity at the time the patient had the sudden abdominal distention, the dyspnea, and the heart failure. He believed the case was a medical one and not susceptible to surgical aid.

NEW YORK ACADEMY OF MEDICINE.

Section on Obstetrics and Gynecology.

Stated Meeting, held December 22, 1904.

Dr. Charles F. Adams, Chairman pro tem.

Specimen of Fibroid Tumor of the Uterus.—Dr. George H. Balleray presented a large fibroid, with a small supernumerary one, which he removed from a patient 33 years old. She had never borne children. She complained of no pain, tenderness, or flowing, and the tumor was removed because of its increasing size. He believed that in patients under the age of 35 years these growths would continue to increase in size, and that they should be removed, but he did not advocate removing every fibroid, He had watched about 60 cases of fibroids, in women over 35 years of age; when the menopause was reached the tumors were found to be as large as cocoanuts, and then they began to decrease in size and were finally absorbed. If he had operated upon these patients, he believed he would have lost a certain proportion of them.

Dr. S. Marx insisted that all fibroids of the uterus, whether in a single or a married woman or after the menopause, that gave sufficient trouble to warrant an examination, should be operated upon and removed. The possibility of malignant degeneration should always be borne in mind.

Dr. Ernest Gallant spoke of the peculiar color, or cachexia, which was seen in cases of uterine fibromata, which were of considerable size and growing, with only slight bleeding, whether subperitoneal or intramural. This peculiar color was difficult of description. The anemia was different from that of malignant disease. He gave it the name of "fibroid toxemia." If these patients were allowed to go on, they became much worse.

Dr. Arnold Sturmdorf said that watching for degenerations or complications was not sufficient. These tumors gave rise to a toxemia of which we know nothing. It had been found in enucleating these fibroids, on splitting the capsule, an exudation of some kind would get into the abdominal cavity, and produce a sepsis of peculiar type.

Ten per cent. of the women with fibroids died as the result of the tumors, directly or indirectly. Forty per cent. of all women with fibroids had some disease of the adnexa. Malignant degeneration occurred and no one could tell when or why. He believed that simply watching and doing nothing was bad.

Dr. Balleray said he agreed with what was said of the liability of malignant degeneration occurring in these growths and that one could never tell just when malignant degeneration was going to occur. If the woman had passed the menopause and the tumor continued to grow, he would operate.

Specimen of Ovarian Cyst.—Dr. George H. Balleray presented this specimen which was of particular interest because of the doubt in diagnosis. The tumor reached to the hypochondriac region, and occurred in a patient 42 years old. The mass was situated on the left side, and extended to, but not beyond, the middle line of the abdomen. It fluctuated. There were no renal symptoms. Nothing was felt in the pelvis. The finger could just reach the lower margin of the tumor. Upon operation a multilocular cyst of the ovary was found, and there were a large number of adhesions. On the left side the tumor was adherent to the descending colon as far as its junction with the transverse portion. The patient made an uneventful recovery.

The After Treatment of Abdominal Section.—This was the title of the paper to be read by Dr. Charles H. Craig, of Boston, but, owing to his absence, a general discussion took place instead.

Dr. Egbert H. Grandin said success in the after-treatment depended largely upon the attention paid to treatment beforehand, and upon the action of the operator at the time the patient was to be subjected to the knife. In his remarks he wished to be understood as ruling out entirely emergency cases. In the average case, the man who looked out for the condition of the kidneys and who got the heart in good condition and who attended to the body's sewer, would be the one who would have less to do as regards the after-treatment. Furthermore, that man who operated expeditiously and who subjected the patient to as little anesthetic as possible, would be the man who would have least trouble in the after-treatment. Given a subject who came to the operating-room with the kidneys properly functionating, with the liver normal, the intestinal canal empty, with the heart properly supported, with an expert anesthetizer, with an operator who secured hemostasis, and who operated quickly, the after-treatment would be a very simple matter. It was in the desperate type of cases that one was called upon to see in a hurry, for instance at midnight, that the after-treatment called for considerable judgment, and there might be differences of opinion as to what constituted proper medication or treatment. Dr. Grandin then spoke more specifically upon the various points.

The average man, he believed, was too much in a hurry to give food, and did not sufficiently respect the condition of the stomach. The less one put into the stomach, the better; we should give the stomach a rest, and a chance to overcome the effects of the anesthetic. He could not emphasize too strongly this point of leaving the stomach alone. In the average abdominal section case, it was not at all necessary to give anything but possibly water for twenty-four, forty-eight, or seventy-two hours. It was his custom to give nothing but plenty of water. If there was intractable vomiting, he wasted no time in the administration of drugs, but washed out the stomach repeatedly in order to thoroughly cleanse it of the mucus and to allow the mucous membrane to regain its tone; then he gave peptonized milk or other easily digested foods.

If the stomach became the seat of intractable vomiting, then the rectum should be utilized for feeding the patient. He advised that the lower bowel be washed out with cold water before the administration of nutrient enemata; then the rectum would absorb the food if given hot and salty. There was no hurry about giving food by the mouth in these cases.

He could recall the time when the opium treatment was very much in vogue, and he had seen many patients die. He remembered when Tait rebelled against the opium treatment and suggested the saline treatment, and then the profession went to the other extreme. Nowadays, they had struck the golden mean. Dr. Grandin's custom now was to wash out the bowels thirty-six hours after the operation with a soap and water enema, increasing peristalsis in order to get rid of that which might be troublesome, such as gases. Opiates were contraindicated in almost every case of abdominal section. Morphine was distinctly and absolutely of value in the differentiating between shock and secondary hemorrhage, and that was the only condition in which he ever permitted injections of morphine to be given. Full doses of morphine given in shock, changed the clinical picture at once; if administered when there was secondary hemorrhage, the picture would not be changed. Another condition in which he used opiates was for the relief of pain; for this he never used anything else but codeine, and in two and a half or three grain doses in suppositories, and repeated in five hours if necessary.

After ordinary abdominal sections, he believed in changing the position of the patient frequently, largely in order to keep the intestines in motion. Posture with proper draining through the vagina (the only proper way to drain), was of great advantage, especially with the head elevated. By so doing the field of operation would soon be converted into an extraperitoneal one.

Dr. Grandin said the average man was very prone to give digitalis and nitroglycerin when exact indications were absent. The nitrites were only indicated when there was tension of the pulse; the greater the tension, the larger the dose of glonoin should be given. Desperate cases required desperate remedies, and he not infrequently pushed nitroglycerin, giving 1-10th of a grain every hour; it should be given in full doses and without fear, because the effect of this agent was so evanescent. Strychnine was a drug that was much abused, and be believed there was but one indication for its use, viz., when the heart failed, and then strychnine was our mainstay, but in heroic dosage, say 1-25th or 1-20th of a grain every two or three hours. Digitalis, especially the infusion, was indicated when there was kidney insufficiency. When the kidneys were not working properly, and the patient was passing an insufficient amount of urine, infusion of digitalis, associated with continuous saline irrigations of the colon, was the mainstay. He believed the giving of sodium and potassium salts did more harm than good; it was like applying the spur to a tired horse.

Dr. Grandin then referred to those desperate cases, met with often at midnight, cases in which the diagnosis of sloughing fibroids should have been made and had not been made, or in which there was intestinal obstruction, or perinephritic abscess which had been treated for something else. In all these cases there was a soiled peritoneum, and these were the cases which caused a great deal of anxiety in the after-treatment. If a chance was given, he believed in administering calomel and soda four or five hours before the patient went to the operating-room; unfortunately this chance was not given in many instances, and then often spastic paralysis of the gut would follow. Salicylate of physostigmine should be given as a routine measure before operating in these cases. If plastic paralysis occurred, tympanites increasing so that the diaphragm could not act, unless something was done and at once death would invariably follow. Here atropine in full doses, given hypodermically, or hyoscine until the pupils were as big as saucers, was of great value, and restoration of patients often occurred when there was but a forlorn hope. Prior to using these drugs he had seen patient after patient die; but since then he had seen many desperate cases respond to these agents and recovery follow.

Dr. Charles Jewett said he had used Dr. Craig's method since May, giving eserine with the view of preventing in-

testinal paresis and mechanical obstruction, with great satisfaction. The patients vomited less, the abdomen was flatter, and the bowels opened easier as by a simple molasses enema. The use of eserine had been very satisfactory to him, as it did away almost entirely with what had been to him a horror, viz., the danger of intestinal paresis and adhesions. Dr. Jewett used this agent at the close of the operation, although he believed Dr. Craig used it during the operation. He believed it might be given with very good effect in cases of tympany accompanying typhoid fever. In doses of 1-40 grain, he thought it was more effective than in doses of 1-60 grain, such as Dr. Craig formerly used. One-sixtieth of a grain should be used for meteorism other than operative.

Dr. S. Marx said that the eserine treatment had been used before Dr. Craig used it, as in acute ileus; the original instruction was to give it immediately and in large amounts. Dr. Craig could claim to have advised it shortly before operation. In acute ileus following operation, it was said that from 1-60 to 1-40 grain of eserine should be given. Dr. Marx's results with atropine had been better than with eserine. He had found the use of eserine in the chronic constipation of women to be of great value. With regard to pain he did not think we should be sparing in the use of morphine. It was not given if the patient was semi-unconscious, but if there was much pain complained of, morphine and not codeine had given him the best of results. It not only relieved pain, but gave a feeling of well-being. With regard to vomiting, he believed that if the patients were well prepared before operation, this would not give much trouble. The differential diagnosis between shock and hemorrhage could not be made in some cases. The peculiar form of shock that was brought to his mind was the post-partum. The most intense shock was that which could be interpreted as spastic paralysis. This had the peculiar picture of an intense internal hemorrhage. He said he did not know how to make a differential diagnosis between spastic paralysis, internal hemorrhage, and shock. If one depended upon morphine to differentiate between shock and hemorrhage, one would lose many patients. With regard to the bowels, Dr. Marx said he took no particular pains about them. In acute appendicitis operations he did not think of causing the bowels to move for at least a week after operation, because he looked upon the lesion as making a weak spot in the gut.

Dr. Joseph Brettauer said that ten years ago he expressed the same views regarding the time to move the bowels after operation, and he had been severely criticised; he advised leaving them alone. He had no doubt that many cases of intestinal adhesions could be traced to causing the bowels to move early. In those cases in which the bowels had been handled a good deal, or in which the intestines were adherent to diseased organs, he said we might have the condition called pseudo-ileus which was not septic, but which might become septic by forcing calomel and salines down. Dr. Bretauer referred to a book which was written eighteen or twenty years ago, in which was described minutely the action of large and small doses of opium on the bowels, and the comparison was made with the action of digitalis on the heart. According to this when we were dealing with a condition in which the nerve centers which supplied the intestines were hyperstimulated, it was an indication to stimulate the inhibitory centers, as by small doses of opium. One-quarter of a grain of morphine begun on the third or fourth day, and given every four hours, had been followed by much greater benefit than anything in the way of drugs, that he knew of.

Dr. A. Ernest Gallant said that when carrying out the orders of the visiting staff in hospitals, it was generally understood that the bowels should be moved thoroughly the second night before operation; the day before operation the bowels should be again moved by a soapsuds enema, and then they should be allowed to remain quiescent the night preceding operation. After the operation he believed in giving the patients all the water they wanted. He was a believer in the use of small doses of morphine; unless the patient weighed over 250 pounds, he never gave as much as 1-4 of a grain. Following operations he said he had been called upon to wash out the stomach only once with the tube. Dr. Gallant then dwelt upon the advantages of the performance of massage of the abdomen. In the use of salt solution he believed better results were obtained from the use of a nine per cent., rather than a six per cent. solution, and that it was absorbed better. With the patient on the right side and the sigmoid and anus on the level, he said it would not be necessary to use the high enema.

Dr. John O. Polak, in speaking of eserine, atropine, and hyoscine, said that they were to be used in two different classes of cases. Eserine was a preventive of distention; after paresis had occurred he did not believe that eserine worked as well as atropine in full doses, or as hydrobromate of hyoscine. Two points of value were omitted. There was no question about the value of eserine shortly after opening the abdomen. Before the patient left the table, a saline enema should be given, something for the intestines to work upon; the expulsion of gas then was very prompt and voluntary. In emergency cases the intestines should be cleared out by enemata; especially if the patient was seen four or five hours before operation, it would work particularly well. Most of these cases were vomiting cases, and ten grains of calomel was of very little value When post-operative vomiting was marked, lavage should be used immediately following operation; by so doing the patients were made more comfortable and did not vomit so much, if at all. It was well to leave a certain amount of fluid within the stomach in order that it might pass on into the intestines; that was an advantage in diminishing the amount of toxemia. The elevated head posture was of value in diminishing vomiting, but was not to be used in cardiac cases, or where there had been hemorrhage, or where the Trendelenberg position had been used. Since May 1, he said he had had an experience with the use of eserine in 80 cases. He had used it before and after operation; he had continued its use for days afterwards, but not as recommended by Dr. Craig. Immediately after the abdomen was opened 1-30 or 1-40 of a grain of eserine was given; after the operation saline solution was left in the bowel. This procedure so far had given him very good results.

Dr. George H. Balleray said that the real value of eserine could not yet be determined, and he thought one should be careful in attempting to ascribe to it any such specific action. If there was much pain or restlessness, opium in some form, should be administered, although he was not in favor of large doses. In all cases in which there was much distention, rectal feeding should be resorted to entirely. He had never seen a patient die from simple distention not accompanied by peritonitis.

Dr. Philander A. Harris of Paterson said that when active peritonitis developed after laparotomy the patient usually died, in spite of whatever might be done for her. In such cases the tympany was generally very pronounced, and the evidences of intestinal paresis were both early and persistent. Four or five years ago he adopted the practice of beginning, whenever possible, the administration of one drachm of sulphate of magnesia thirty-six hours before operation, with instruction to repeat the dose every hour until the bowels had moved four times. In some cases there were but four or five movements, but more often the bowels moved eight or nine times. Patients thus prepared, suffered very little from intestinal fermentation and consequently were generally free from tympany after abdominal section. Sometimes the bowels would move after operation, without enema, but as a rule he gave an enema or a low intestinal irrigation on the third or fourth day after laparotomy.

The most important item in the after-treatment of abdominal section was the discovery of internal hemorrhage. A close and frequent study of the pulse was the most im-

portant duty. Whenever a great deal of intra-abdominal hemostasis had been necessary, it had been his custom to take the pulse every twenty minutes for the first twenty-four hours, and leave word that should the pulse at any time go twenty beats faster than the lowest pulse recorded for that patient after the operation, he must at once be notified. If investigation led him to believe that there was bleeding within the abdominal cavity, he at once reopened the incision and inspected the field of operation. He had found that many trained nurses were unable to count correctly a pulse-beat when it was weak and more rapid than one hundred and twenty-five per minute and he [illegible] to allow such nurses to assume the care of these cases.

Dr. Sidney D. Jacobson said he had had good results from the use of 1-75 grain of atropine in the prevention of post-operative paralysis, as had been suggested to him by Dr. Brettauer. This agent checked glandular secretion and less mucus was to be found in the stomach. Its action upon the muscular coat of the intestine prevented flatus from gathering in the bowel.

Philadelphia Neurological Society.

At a stated meeting held December 27 Dr. Ralph Pemberton exhibited for Dr. Charles K. Mills "A Case of Rhizomelic Spondylosis," demonstrating the alterations in the joints and component structures by means of skiagrams. Dr. S. D. Ludlum exhibited "A Case of Spastic-ataxic Paraplegia Developing After Childbirth." Dr. J. W. McConnell exhibited "A Case of Senile Neuritis" and also "A Case of Hemianesthesia, Hemiataxia, Hemiastereognosis, Hemiathetosis, and Hemianopsia Due to a Sudden Cerbral Lesion." In the latter the patient was found in a dazed state without loss of consciousness or convulsion or loss of power or noteworthy alteration in the reflexes. The symptoms suggested a lesion in or about the optic thalamus. Dr. C. S. Potts reported "A Case of Traumatic Cervical Hematomyelia." The patient was a colored man who had fallen and fractured his skull. There was extensive weakness and impairment of sensibility in the trunk and the upper and lower extremities. After death the lower portion of the cervical cord was found compressed and the seat of hemorrhage. Dr. C. D. Camp presented a communication entitled "The Pathology of Tabes" and one on "Fibrous Nodules of the Pia." The latter condition simulated miliary tuberculosis. Dr. A. R. Allen read a paper entitled "Annular Degeneration of the Spinal Cord," describing the histological findings in a case of this kind. Dr. T. H. Weisenburg read a paper on "Pseudobulbar Palsy," reporting six cases of this disorder with the post-mortem findings in three. The lesions were not always confined to the cerebrum, being found sometimes in the peduncles, the pons, and the medulla.

Philadelphia County Medical Society.

At a stated meeting held December 28 Dr. H. W. Wiley, Chief of the Bureau of Chemistry of the United States Department of Agriculture, presented a communication entitled "Food-preservatives and Food-adulteration." He spoke first of primitive methods of preserving food, as by means of vinegar, sugar, wood-smoke, and the like, and admitted the necessity of adopting some such course in order to provide for seasons when fresh food is not attainable. He took the ground that when food is treated in any manner, as for instance by coloring matter, to improve its appearance or mordaunts to retain its natural color, or by antiseptics and the like to prevent decomposition, a statement of this fact should be made on the label of the food-product thus offered for sale.

W. W. Smithers, Esq., of the Philadelphia bar, read a paper entitled "Defects in Pennsylvania Food-legislation," in the course of which he criticised severely the methods in vogue for the enforcement of the food-laws, which in their present form he considered unconstitutional. He held that while the provisions of existing laws afford some measure of protection to the people at large they are to a greater extent made the instruments of private gain, political power, individual oppression, and unwarranted interference with trade. He made a plea for the abolition of the office of Dairy and Food Commissioner, for the passage of an act enabling each county or municipality to appoint food inspectors as provided for by the Constitution, for the repeal of the act of 1895 and the enactment of a rational food-law based upon the preservation of the public health and protection against fraud.

Dr. Thomas L. Coley read a paper entitled "The Evaluation of Evidence as to the Pharmacological Action of Food-preservatives." He contended that the researches heretofore made as to the harmfulness or otherwise of certain commercial preservatives have not been demonstrative and he took the position that if the quantity and the character of the preservatives used were restricted to certain limits and the articles properly labeled as to their constitution the public would be in a position to decide the matter for itself.

New Instruments.

VERMIFORM APPENDIX INVAGINATING PROBE.

By H. J. BOLDT, M.D.,
NEW YORK.

It has become customary with many surgeons when opening the abdomen, even for another purpose than that for the removal of the vermiform appendix, to remove also or to invaginate that seemingly useless structure. I prefer invagination or inversion to appendectomy, whenever the former can be done. To overcome the inconvenience accompanying the customary methods, I have had a very small spur attached to an ordinary silver surgical probe. After the mesoappendix is tied off and all particles of

mesoappendix are stripped off from the appendix, the spur is inserted into the tip of the latter. This prevents the probe from slipping off and the inversion can now be readily accomplished in a few moments. One suture over the opening closes it, and then this suture is usually tied together with the ligature which was used to tie off the mesoappendix. Having found this simple little device, made on my suggestion by the Kny Scheerer Co., of such practical utility, I place it before the profession for trial. The small point should not be more than a millimeter long and as thin as the point of a cambric needle.

39 East Sixty-first-Street.

The Influence of Becquerel Rays on the Skin.—Halkin attached a radium capsule by a piece of plaster to different areas of the skin every day for from one to two hours; at the end of thirty-eight days, all these points were simultaneously excised. A patch exposed for two hours showed a livid discoloration, which disappeared on pressure. At the end of twenty-five days microscopic changes were very characteristic. The effects were visible upon the vessels at the end of eight days, later upon epithelial and connective tissue cells presenting certain analogy to those produced by *x*-ray. He finds that the action is too superficial to be of use in lupus vulgaris.—*Archiv für Dermatologie und Syphilis.*

Books Received.

Die Farbetechnik für das Nervensystem. Von Dr. Bernhard Pollack. Third Edition. 8vo, 150 pages, paper. S. Karger, Berlin. Price, M. 3.50

Being Done Good. By Edward B. Lent, Esq. With a foreword by Charles M. Skinner, Esq. Second Edition. 8vo, 345 pages, muslin. The Brooklyn Eagle Press, Brooklyn, N. Y.

Ten Lectures on Biochemistry of Muscle and Nerve. By W. D. Halliburton, M.D., F.R.S. 8vo, 160 pages, illustrated, muslin. P. Blakiston's Son & Co., Philadelphia. Price, $2.00 net.

A Laboratory Guide in Histology. By Charles H. DeWitt, B.S. 8vo. 88 pages, illustrated, muslin. Charles H. DeWitt, Valparaiso, Ind.

Totals	1,376	261

Causes of Cardiac Insufficiency.—Joseph H. Pratt refers to Bamberger as being the first to recognize that this is a muscle insufficiency. In cardiac insufficiency there is a disproportion between the heart's capacity for work and the proportion between the heart's capacity for work and the work to be done. It may be that the working power of the heart is diminished, or, again, the demands made upon a healthy heart may be so increased that its functional capacity is inadequate. In either case the result is cardiac insufficiency. The cardiac incompetency is due either to the inability of the heart to dilate sufficiently to receive all the blood that flows from the veins, or to the inability to propel the blood onward with proper velocity. The condition of the heart muscle determines the clinical course of chronic valvular disease. The great variations in these cases depend more upon the condition of the cardiac muscle than on the valvular defect. The working power of the heart is dependent upon the contractility of the muscle fibers and the elasticity of the cardiac wall. Any cause, therefore, which diminishes the contractility and the elasticity, will tend to produce cardiac insufficiency. Fatty metamorphosis has been thought to be the most common cause of cardiac weakness. The term fatty heart refers both to an increase of adipose tissue between the heart fibers, and to a deposit of fat droplets within the muscle cells. The former condition is generally known as fatty infiltration and the latter as fatty degeneration. Many authorities consider the fatty metamorphosis as a most serious alteration in the structure of the heart. The writer states that his interest was aroused in this subject not only by the frequent occurrence of marked fatty degeneration at autopsies, but also because no relation seemed to exist between fatty heart and cardiac weakness. He has found in his investigations that extreme fatty metamorphosis can be present without producing symptoms and in some cases in which cardiac weakness had been prominent the myocardium contained little or no fat. A heart which contains very little blood but no fat has a yellowish hue and may easily be mistaken for a fatty heart. Recent writers assert that fatty degeneration is rare in chronic heart disease. The writer has examined the evidence furnished by anatomical, chemical, and experimental investigations without finding any support for the theory that fatty metamorphosis of the heart is the cause of cardiac insufficiency. The writer asserts that no justification exists for attributing cardiac insufficiency to nervous disturbances or exhaustion. The results of recent work indicate that the circulatory disturbances which occur during the height of the febrile period in the infectious diseases are probably due less to cardiac insufficiency than to paralysis of the vasomotor center in the medulla. The writer concludes by stating that in the light of present knowledge certain anatomical alterations, especially coronary sclerosis and acute interstitial myocarditis, must be regarded as the most common causes of heart failure.—*Bulletin of the Johns Hopkins Hospital.*

Gonorrheal Salpingitis in a Child Aged Six; Gonorrheal Inflammation of the Uterine Appendages in a Girl of Three and One-Half Years.—Leonard A. Bidwell reports the first case, and George Carpenter, the second. In the case of the first patient, inflammation of the vulva and painful micturition were observed at the beginning of the illness. Within a few days the right foot began to swell. There was redness and edema over the flexor tendon sheath, and pain on movement. On the following day an incision was made and some clear fluid was evacuated from the tendon sheath. Examination showed that the pus was issuing from the os uteri. Gonococci were found in the discharge. Abdominal symptoms developed and operation was decided upon. Some slightly purulent fluid was found in the peritoneal cavity, and some flakes of lymph on the intestines. Both tubes were full of pus, and so were removed after ligature of their ends for sterilization will result. In case of gonorrheal vaginal discharge did not completely cease after the operation, and still contained gonococci. The os was dilated and the uterus curetted. Within a week after this the discharge ceased and the child was in perfect health. The writer believes that in such cases an operation should not be done until all hope of cure by other means has been abandoned, for sterilization will result. In case of gonorrhœal vaginal discharge, the patient should be anesthetized, and if it is found that the discharge comes from the uterus, the uterus should be curetted in order to avoid any extension to the tubes. The affection of the foot was undoubtedly a form of gonorrheal rheumatism. The second child when first seen by the writer had suffered from a vaginal discharge of six weeks' duration. There were pains in the lower part of the abdomen, which was not swollen. Micturition was frequent. Pus from the vulva contained numerous gonococci. Bimanual examination of the pelvic viscera was made by way of the rectum and the uterine appendages were found to be involved. All of the parts had rather a woolly and indistinct feel, which was thought to be due, possibly, to associated peritonitis. A month later the pelvic condition had changed considerably for the better All parts were freely movable. There was still a purulent discharge from the vagina. The writer thinks that the pelvic disease was secondary to gonorrhea. He believes that there were pelvic peritonitis and salpingitis, certainly on the right side and probably on the left. There was apparently spontaneous recovery. Marx believes that these infantile inflammations are apt to commence afresh at puberty, and are often the real cause of pelvic inflammations of newly married women. The writer emphasizes the value of bimanual examination of the internal genitalia in young children.—*The British Journal of Children's Diseases.*

Tuberculous Peritonitis.—C. H. Mayo bases the statements made in this paper upon 144 operations for the relief of tuberculous lesions involving the peritoneum. Fifty-nine operations were performed for tuberculous peritonitis died. There were 58 operations for the removal of tuberculous tubes, with 56 recoveries and 2 deaths, and 27 cases of tuberculous appendicitis without a death. Peritoneal tuberculosis was found 284 times in 13,922 necropsies, as collected by Grawitz and Bruin. Although this form of tuberculosis is always due to the tubercle bacillus, it is practically always secondary to tuberculosis in other regions. Infection reaches the peritoneum most commonly through the tubes, the uterus, the appendix, or a perforating ulcer. The peritoneum is more resistant to this than it is to other infections, and when the primary focus is removed, it is capable of wonderful repair. About five women are afflicted to one man. The most common period of life for this affection is between the ages of twenty and thirty. A tuberculous family history is reported in from 30 per cent. to 71 per cent. The peritoneal type is generally classified as follows: miliary with ascites, the adhesive or fibro-plastic, the suppurative or mixed infection, and the nodular. The larger number of the infections are found in the lower half of the abdomen. Oftentimes the only diagnosis possible is a tumor or a condition of the abdomen which it will be safer to explore than to leave. In most cases, however, a fairly exact diagnosis is possible. The excellent effect of operation in many cases is well known. The writer states that in all cases where it is at all warranted by the patient's condition, he attempts the removal of the primary focus of leakage or infection. The peritoneal condition is left to cure itself, and the abdomen is closed without drainage. In some cases operation would be extremely hazardous. In males, the writer makes the incision over the appendical region, while in women it is so made that the pelvis can be explored. Great care must be taken not to open the bowel. It is generally best to keep close to the parietal or pelvic peritoneum, separating as few adhesions as possible in exposing the region affected.—*Dominion Medical Monthly and Ontario Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended January 13, 1905:

SMALLPOX—UNITED STATES.

			CASES.	DEATHS.
District of Columbia, Washington	Jan.	1–7	2	..
Illinois, Chicago	Jan.	1–7	16	..

PATHOLOGICAL CHARACTERS, DIAGNOSIS, AND EPIDEMIOLOGY OF BUBONIC PLAGUE.

BY MARK JOHNSTON WHITE, M.D.,

PASSED ASSISTANT SURGEON UNITED STATES PUBLIC HEALTH AND MARINE HOSPITAL SERVICE.

THIS article is based on my observations of pest among white persons, Asiatics, animals, and insects in California, from April, 1901, to December, 1902, and more recently in Honolulu and Hong Kong.

B. pestis, like its biochemical homologue, *B. typhosus,* exhibits special preference for lymphatic tissue. Acting on the highly organized encased lymph-nodes, it produces the anatomical character peculiar to plague, just as *B. typhosus,* attacking the less completely organized nonencapsulated areas of lymphatic nodules, produces the anatomical character peculiar to enteric fever. But its action is not limited to the lymphatic system, although the mesodermic tissues are those affected most. Along with certain other tissue-preferring organisms it is accredited with the ability to produce pneumonia. It appears, too, that plague, like enteric fever, sometimes occurs without demonstrable lesions of the lymphatic or pulmonary tissues, and so a third clinical variety, the septicemic, is recognized. Other tissues, as is usual in acute infections, show parenchymatous and fatty degenerations.

The bacilli being absorbed by the lymphatics from the mucosal or cutaneous atria of infection, cause bubonic enlargement of the intercallated nodes, but it is probable that a typical bubo may also result from infection through the blood-vessels as well as through the lymphatics. Toxemia invariably is present, and it is almost invariably true that a demonstrable bacillemia occurs very early, even before a distinct subcutaneous bubo. Plague without characteristic lymphadenal lesions is of rare occurrence, as is the case with enteric fever. I have examined cases clinically without finding any evidence whatever of bubo, and post-mortem examination has demonstrated its entire absence in all of the subcutaneous, the internal and external iliac, the lumbar, and the mesenteric nodes; but upon removing the very heavy covering of the deeply seated celiac nodes, I have demonstrated its typical presence, thereby setting aside the clinical and "ordinary post-mortem" diagnosis of "septicemic plague without bubo." But it is possible that a quickly fatal termination may occur even before the primary lymphagenous bubo has time noticeably to develop, so that a bacillemia only is demonstrable. In other clinically septic cases, the lymphadenal involvement, not observed during life, has been found post-mortem, in the lingual and pharyngeal tonsils and the consecutively, though not extensively, involved deep cervical and retropharyngeal nodes.

There are many cases of plague in which the conditions preceding the development of the subcutaneous bubo, rather suggest that the organisms entered the nodes through the afferent blood-vessels and not through the lymphatics from the skin. Unquestionably, the bacilli may enter through the skin as well as through the alimentary mucosa, and similarly involve the related lymph glands; but analogously and experimentally, it would appear reasonable and likely that some evidence of such cutaneous portals would be demonstrable, at least during life if not at the post mortem; and so there is in some cases, but not nearly so uniformly as in the case of other bacteremias following skin infections. The infection aspects of plague and anthrax may be noted. The evidence of dermic inoculation in severe anthrax is the characteristic malignant pustule, while in the very mild cases it is a promptly healing, though demonstrable, papulovesicular lesion, both of which precede the lymphadenal involvement and the general symptoms. In anthrax edema, there is no demonstrable infection—atrium, and the general symptoms may precede rather than follow the lesion. Experimentally the cutaneous infection-atria of plague are well marked, but naturally they are, when present, more nearly like that of very mild anthrax. In the majority of subcutaneous plague buboes, however, the skin, as in anthrax edema, shows no infection atria, and commonly the constitutional symptoms precede the development of the bubo. In internal anthrax the infection-atria and the clinical sequence are comparable to plague infection, the onset being with diarrhea and vomiting, followed by bacteremia and skin lesions, some of which may be suggestive of infection-atria. And if a variola-like papulovesicular lesion should be present on the lymph-shed of a plague bubo, the disposition to consider it the portal of infection would, in many instances, predominate. Clinically and at necropsy I have carefully searched for cutaneous infection-atria, and have particularly interrogated patients, yet no direct evidence could be found in the great majority of cases to show that they ever existed. Nevertheless, the possibility that minute atria may occur and completely heal, even without the patient's or clinician's knowledge, should be kept in mind. The common and early association of the pneumococcus with *B. pestis* in the buboes and heart's blood, first directed my attention to the upper alimentary mucosa, from which the cocci readily might invade the blood through the lesions caused by the bacilli. And while lymphagenous infection more naturally and satisfactorily explains the occurrence of any bubo, hematogenous infection in the case of certain subcutaneous plague buboes deserves thorough consideration. In such cases the sequence of invasion may be: (1) mucosal infection-atrium; (2) primary or lymphagenous bubo; (3) bacillemia; (4) secondary hematogenous or metastatic bubo, in the adenoid tissue of which the bacilli, rapidly multiplying, pass along with the newly formed leucocytes into the lymph-channels, and through them subsequently invade the other nodes of the bubo chain, all of which, along with the

other lymph nodes throughout the body, have suffered previous attack by the circulating toxins and bacilli.

The Pathological Characters.—The three clinical varieties, the bubonic, the pneumonic, and the septicemic may be defined pathologically as follows:

1. *Bubonic or Lymphadenal Variety.*—This is a regional lymphadenitis or "typical bubo," characterized anatomically by a chain of hemorrhagico-necrotic nodes embedded in serohemorrhagic edema.

2. *The Pneumonic Variety.*—This occurs as a lobar or lobular consolidation essentially indistinguishable, histologically, from pneumococcal and other bacterial pneumonias.

3. *The Septicemic Variety,* which is a bacillemia without the association of pneumonia, lymphadenitis, or other gross lesions resulting from bacterial activity.

Post-mortem Findings.—External features common to all varieties. Most victims are noticeably well nourished, but a few are only fairly or poorly so, yet in all of them there are quite commonly observed the following: (1) Firmly contracted calves with extended adducted feet. (2) Firmly flexed and adducted thumbs, their tips approximating the third metacarpophalangeal joints. Occasionally the thumbs are abducted and hyperextended. (3) The little fingers are fully flexed and their tips strongly apposed to the outer borders of the hypothenæ. The rigidity of this little finger contraction is very noticeable and constant. The other fingers are not so completely flexed and are far more easily extendable. General post-mortem rigidity is well marked during the first twenty-four hours. (4) Suffusion of the face, ears, and neck. (5) Small conjunctival hemorrhages of a dirty light brown color most numerous in the line of the palpebral aperture. (6) Rapidly appearing general lividity beginning shortly after the removal of the clothing and free exposure of the body to air within three hours after death. (7)) Pest eruption characterized by distinct purpuric spots varying in size from 1 to 3.5 mm. upon the surface, and from .5 to 1. mm. in depth; in color from a fading pale red in the irregularly shaped larger ones to a bluish-purple shade in the oval medium, and a growing red in the round, smaller, and apparently younger petechiæ. They are discreetly and generally scattered over the body, but most numerously over the lower thoracic and upper abdominal regions where from 25 to 40 may be counted in the relative proportion of 2 of the smaller to 3½ of the medium and 1½ of the larger ones. The bluish-purple shade is most intense upon the forearms. (8) Marks of counter-irritation over the arms, neck, chest, and abdomen anteriorly in patients of Chinese physicians, who frequently employ three methods of counter-irritation in the treatment of plague and other acute febrile diseases of severity. The coin and salt method, usually applied to the arms and chest causes large cutaneous ecchymotic patches, and in plague cases, diffuse hemorrhages into the deeper soft structures. The twisting pinch method produces similar lesions, but of smaller area. The "black tan" method consists in pricking the skin over areas of about 5 mm. in diameter and usually along the anterior middle line of the body. Ordinarily, one pricking is over the manubrio-gladiolar junction, a second over the xyphoid cartilage, and a third above and near the umbilicus. At necropsy they usually are black-crusted and dusted over with a reddish-brown powder. (9) Polylymphadenitis characterized by palpable and occasionally visible enlargement of the lymph nodes of the body without appreciable exudation or hindrance to their movability. (10) A distinct plague odor for the appreciation of which experience is necessary.

Additional features are observable where there is a typical bubo subcutaneously. The overlying skin, especially in the cervical and inguino-femoral regions, is usually very tense and glistening. Frequently it presents a large, light yellow, sharply defined, irregular, barely elevated area, apparently caused by slight cutaneous edema and the underlying subcutaneous pressure. The bubo has a peculiarly brawny, infiltrative firmness, and it is distinctly an acute lesion characterized by marked lymphadenitis embedded in an extensive subcutaneous, caky exudate, and usually unaccompanied by any explanatory infection-atrium, lymphangitis, or phlebitis. One of my patients had phlebitis (long saphenous), but none had lymphangitis. When present, lymphangitis is usually attributed to other organisms on the score that "*B. pestis* causes necrosis, but not inflammation."

In the inguino-femoral region the periglandular edema may extend from near the umbilicus to the knee, and from the anterior superior iliac spine, to the scrotum and prepuce. In the axilla, it may extend over the entire axillary, lateral, anterior thoracic, and sternal regions, and to the base of the neck. In the cervical bubo, the edema usually involves the entire side of the neck, crosses the anterior median line and extends into the cheek, anterior and posterior auricular tissues. When the lingual and pharyngeal tonsils are affected the edema usually involves the uvula, faucial pillars, epiglottis, vocal cords, and posterior pharynx.

Section of a regional lymphadenitis or typical bubo reveals very striking lesions. The commonest, or inguino-femoral bubo, is usually but the external end or beginning of the chain of characteristically and progressively affected lymph nodes. Ordinarily, the chain is composed of the superficial and deep inguinal, the external iliac and the median lumbar nodes, but occasionally the iliac and lumbar nodes escape noticeable involvement as the result of early death or arrest of the process. Section of a unilateral bubo involving these nodes and their surrounding tissues reveals the following:

1. *The Nodes.*—Those of the *superficial inguinal* group vary in shape and size from a bean 8 mm. in length to a marble 25 mm. in diameter and in color from a pink to a mottled purple shade. They are soft, swollen, tense, and of uniform consistency. The smaller ones are movable, while the larger ones are firmly embedded in the infiltrated periglandular tissues. Upon section, the smaller glands show cortical injection, with an occasional small cortical hemorrhage. The cut surface of a large one shows a dirty gray-colored, succulent cortex with discreet ovoidal hemorrhages varying from .2 to .6 mm. in length, and clearly distinguishable from the wet, pulpy, dull-brownish-red medulla with crops of necrotic areas, and a uniform consistency much softer than the uniform consistency of the cortex. The *deep inguinal* nodes are larger, being of the shape and size of a hen's egg or an English walnut. They are of a diffuse purple-red or bluish color, tense and immovable. Their cut surfaces are very soft and of uniform consistency and color, but marked by numerous areas of necrosis and bars of fibrous septa. The delineation of the cortex and medulla is impossible. The *external iliac and lumbar* nodes are somewhat smaller than the deep inguinal, and they assume the general shape of an enlarged turtle's egg. In color they are darker, and in consistency very much softer, for upon sec-

tion their contents frequently are found to be almost semifluid, and of a dark-brown chocolate color. This was particularly well marked in the case of a white man who, while recovering from the bubonic type with the aid of Yersin's serum, succumbed to the rapidly developing pneumonic type.

2. *The Surrounding Tissues.*—They are swollen, edematous and hemorrhagic. The edema immediately surrounding the *subcutaneous* nodes is serohemorrhagic, but at points varying from 30 to 50 mm. distant it fades into a serogelatinous type. The bloody serum exuding upon section fills the wound and floats upon its surface many flat globules. The *internal or retroperitoneal* periglandular edema, is decidedly hemorrhagic, and indeed constitutes a plainly visible, diffuse, black, succulent blood clot extending from Poupart's ligament to near the lower border of the kidney, and from the mid-spinal line to near the middle line of the loin. Like the subcutaneous edema, it has a serogelatinous periphery, most observable in the post-renal and anterior abdominal tissues, and fringed by discreet and fairly numerous peritoneal hemorrhages. Externally, the serogelatinous element predominates over the hemorrhagic, while internally the reverse obtains. The larger arteries traversing such a bubo show no gross lesions in the media or elsewhere, but their accompanying veins, in noticeable contrast, almost constantly present numerous discreet and, at points, confluent medial hemorrhages. This is especially marked in the external iliac and lumbar veins, and, to a less degree, in the femoral. The sheaths of related nerves occasionally show long hemorrhagic bands. The underlying muscles are very pale, soft, swollen, edematous, and easily torn. The urethral mucosa is injected, but not hemorrhagic. The vas deferens sometimes is discreetly hemorrhagic, while occasionally there is an acute hemorrhagic epididymitis, with noticeable tendency to orchitis.

It may be observed that the virulence of this process is progressive, as the consecutively involved nodes and their surrounding tissues are more hemorrhagic, necrotic, and disorganized than are the structures first attacked, and such is the case no matter where the bubo-chain occurs. In explanation, it may be noted that lymph nodes throughout the body are affected early by the circulating toxins, while those nodes of the bubo-chain are, in addition, subjected to a progressive lymphagenous invasion by lymph-node-born-and-nourished bacilli, whose pioneer ancestors may have first effected favorable lodgement through the lymph vessels from the skin, or through the blood-vessels, with subsequent entry into the lymph stream along with the newly made leucocytes.

In some cases, and in very fat persons, the bubo appears much smaller, so that palpation does not reveal such distinctive periglandular edema, or swollen nodes. In such cases, however, there is, ordinarily, an appreciable fullness of the region that is especially noticeable on oblique inspection. Failure to palpate a bubo, especially in a fat person, by no means indicates its absence.

The lesions of an inguinofemoral bubo are well shown by a long incision approximately perpendicular to the middle of Poupart's ligament, and extending from near the umbilicus to the middle of the thigh, bisecting Scarpa's triangle and including all tissues down to the bone. After completing the examination of this longitudinal section, extend the usual anterior median incision outward along Poupart's ligament to and beyond the anterior superior iliac spine, cutting through the entire belly wall along this line. This gives an obliquely transverse section of the bubo, and brings into full view the position of the consecutively involved retroperitoneal nodes and their strikingly hemorrhagic surroundings.

Ordinarily the subcutaneous bubo is unilateral, but sometimes characteristic ones exist bilaterally. In other instances there may be an axillary and an inguinofemoral, or a cervical, axillary, and femoral, or celiac and femoral, together with, of course, the general polylymphadenitis, and in the majority of instances primary lymphagenous buboes, connected with the alimentary mucosal atria. The primary bubo commonly involves the celiac nodes or the lingual and pharyngeal tonsils. The latter are but moderately enlarged, somewhat edematous, and in places hemorrhagic. The lingual tonsils, however, may show very distinct or but moderate involvement. The peritonsillar tissues are especially edematous, and the infiltration may extend to the faucial pillars, uvula, epiglottis, vocal cords, and posterior pharynx.

Ordinarily this tonsillar process is bilateral, but usually it is most marked on one side. The deep cervical nodes are consecutively involved, dark purple-red in color, and frequently semifluid. In size they may remain small and not palpable through the skin, or they may be very large. In either case the surrounding edema of the soft parts, together with the damaged nodes, indicates a typical bubo. The retropharyngeal nodes are similarly involved, and, as a rule, are but moderately enlarged. These lesions also indicate the progressive virulence of the process.

The primary or lymphagenous bubo also occurs in the deeply-seated celiac nodes, the portals of infection being in the pyloric stomach and upper duodenum. The lesion is not demonstrable until its heavy covering is dissected away, and hence it may be overlooked. Here the mucosal infection-atria are well marked and the bubo-chain typical. In size it may be small, medium, or large, just as any other bubo, whether lymphagenous or metastatic.

The Pneumonic Variety.—Anatomically and histologically the pneumonias of plague are substantially indistinguishable from those caused by the pneumococcus or streptococcus, or by other bacteria, or by protozoa. Pneumonia plague has been classified because the onset and clinical course of pest sometimes are characterized like enteric fever, by signs and symptoms of pneumonia, associated with plague bacilli in the sputum, which may have been derived from the linguopharyngeal or the pulmonary lesions. And furthermore, because the pneumonic areas are found post mortem to be rich in plague bacilli.

Ordinarily the type is lobular, but sometimes lobar or semilobar. The entire lung is markedly edematous, and the pleural covering of the consolidations noticeably roughened. Plague pneumonia is believed to occur with or without the coexistence of a bubo, and either early or late in the attack. Infection is thought to be by inhalation or by aspiration, but it could readily occur through the blood, as the pneumonia of measles is sometimes believed to arise, especially as there is an early, not [illegible] pneumococcemia in large bulbar cases without pneumonia. Such pneumococci may or may not find favorable lodgment in the lung. The possibility of bacterial succession in this variety may be profitably considered. The pneumococcus is very constantly associated with *B. pestis* in the pulmonic consolidations, and it may be that it exerts

the primary and principal bacterial action in the production of the lesion, the pest organism being a secondary and etiologically unessential invader from the blood, but symbiotically more active than the causative cocci, and therefore in course of time appearing in overshadowing numbers, both in the sputum and the pulmonary consolidations. The consecutive examinations of the sputum in this variety are somewhat suggestive, as the cocci, very noticeably predominating at first, gradually decrease in numbers as the plague bacilli steadily increase.

The Septicemic Variety.—This is supposed to be a primary bacillemia without the occurrence of a bubo, pneumonia, or other gross lesions. I am strongly inclined to believe that a painstaking search of all lymphnodal regions, especially those of the deeply seated thoracico-abdominal nodes, and the lingual and pharyngeal tonsils, will reveal the fact that plague, primarily, is a disease of the lymph nodes, and that non-bubonic cases are quite as rare as typhoid fever without primary lymphatic involvement. The undermentioned secondary changes occur in the various other tissues of the body in all clinical varieties:

1. Polylymphadenitis, characterized anatomically by moderated enlargement and cortical injection of the nodes, but without demonstrable periglandular edema. Some of these nodes may be almost the size of a pigeon's egg, and present several cortical hemorrhages, or what may be termed the first stages of metastatic or hematogenous bubo-formation. The nodes are movable and allow easy extirpation without rupture of the capsules. In color they vary from a pink to a purple-red shade, or better, bluish-purple. This condition is similar to that more or less commonly observed in other acute infections, like measles, scarlet fever, pneumonia, and it may be regarded as due principally to the circulating toxins, and perhaps to an occasional organism that may or may not find bacteriolytic conditions favorable to its further successful invasion and attack.

2. The spleen may be much enlarged, diffluent, and almost semifluid, or but moderately enlarged without bulging of the pulp upon section. Commonly there is a mild grade of acute perisplenitis, with occasional wedge-shaped infarcts. Not infrequently the organ has the distinct characteristics of acute streptococcal spleen, but at times it may appear practically normal.

3. The pancreas is negative, except when the celiac nodes are extensively involved, when the head may be hemorrhagic by contiguity.

4. The liver is somewhat swollen, and presents on the upper surface of the right lobe light yellow irregular subcapsular patches of necrosis, varying from 6 cm. to 15 cm. in diameter. Upon section these may be shown to be continuous, with more diffuse, deeply seated areas, or they may extend but a few millimeters into the parenchyma. Fatty degeneration is the rule. Commonly there are diffuse hemorrhages into the lateral and suspensory ligaments at their hepatic attachments. Acute nephritis and swollen adrenals are common lesions. The bladder is contracted and usually contains a few cubic centimeters of mucoid urine. Ureters, prostate gland, penis, and testicles present no characteristic lesions. Occasionally the epididymis is hemorrhagic. Vagina, uterus, and tubes are not affected. The ovaries are very much injected.

5. The lungs show marked edema and hypostasis, with or without pneumonia. The bronchial mucosa is very much reddened. Sometimes there is acute plastic pleurisy, and not infrequently simple hydrothorax, bilaterally.

6. The left heart is firmly contracted, the right moderately dilated. Acute and well-marked myocarditis, with scattered sub-epicardial hemorrhages, is a constant lesion. The blood-vessels, except as already noted, are unaffected. The blood is very fluid and dark.

7. Gastrointestinal tract: The tongue is swollen and covered by a dark mahogany-brown fur. Its lymphadenoid tissue is noticeably swollen and at times very markedly so. Gastric contents are frequently found in the unaffected esophagus. The stomach mucosa is reddened and usually thrown into longitudinal folds, the crests of which are hemorrhagico-necrotic, and not infrequently present long superficial ulcers that extend the length of the viscus. Such ulcerations are confined to the mucosa, and are the result of numerous small hemorrhages that coalesce to form long hemorrhagic strips which subsequently necrose and ulcerate, aided perhaps by gastric juices. In other cases the mucosa is not thrown into rugæ, but presents numerous discreet hemorrhages, most marked in the cardia. The upper duodenal mucosa is usually injected and hemorrhagic. Ordinarily, there is an acute catarrhal enteritis, with very tenacious mucous. Peyer's patches occasionally exhibit the shaven-beard appearance, but I have never noticed any inflammatory involvement of this tissue or of the usually distinct solitary follicles, or the mesenteric nodes. A golden-yellow serous edema is frequently found at the thymus gland site. The thyroid gland is somewhat swollen. The solitary glands are not involved. Cases of pest parotitis have been reported, but the deep parotid lymphnodes are sometimes consecutively involved, giving the *superficial* appearance of a "parotid bubo."

The skeletal muscles are moist and reddened. The skin, bones, periosteum and joints appear to escape noticeable lesions.

Administrative reasons prevented me from examining the cerebrospinal system, bone marrow, interior of joints, etc.

Plague in Insects, Rats, and Other Animals.—The most noticeable post-mortem appearance of the plague-rat is the engorgement of the subcutaneous blood-vessels, together with a diffuse pink color of the subcutaneous muscles, which have a peculiarly dry, waxy translucency. The spleen is soft and the lymph-system may show isolated buboes, but not bubo-chains, as in man. Nor is the extent of the periglandular edema nearly so great as that about a bubo-chain. Intestinal infection is marked by inflammatory induration of the intestinal wall. I have never recognized a case of chronic plague adenitis, but it is reported to be of vast epidemiological importance. Plague bacillemia is, as a rule, well marked. Pestlike colon-group bacilli are frequently found in dead rats, and it is wrong to make even a provisional diagnosis of plague, because a bipolar, Gram-decolorizing bacillus is present and fairly numerous. Especially is bacterial confirmation essential. Similar organisms also appear in dead cats and in the marketed lungs and other viscera of swine.

In other animals, such as calves, sheep, hens, pigs, ducks, turkeys, geese, and pigeons, the lesions are those of hemorrhagic septicemia. Infection of poultry is through the alimentary tract, and so with the animals, but they are also susceptible to infection by cutaneous inoculation. After feeding on plague tissues, from 3 to 6 weeks may elapse before such animals and poultry show visible signs of plague. And this matter is of much importance, epidemiologically.

Flies die in from 6 to 8 hours after feeding, the

principal symptom being profuse diarrhea and restlessness. Cockroaches and bed-bugs have intestinal plague, but are more resistant than flies.

Diagnosis.—*Clinical.*—The facies and tongue are indicative. The facial aspect indicates that the patient is "inwardly aware" of all that is transpiring, and that he is making a determined will-power resistance to the attack. There is an element of anxiety, secondarily and incidentally about his life, but primarily about the progress of the will-power fight, and the noticeably injected conjunctivæ add materially to the peculiar, hieroglyphic countenance. The tongue, at first pearly white-coated, soon becomes covered with a thick, very moist, mahogany-brown coating most marked along the center posteriorly. The borders are pale-red and the organ is somewhat swollen. The early coexistence of such facies and tongue, especially when the severity of attack is marked, is almost pathognomonic, and particularly if there are very severe headaches and injected conjunctivæ.

Additionally, in the lymphnodal variety, the bubo, if subcutaneous, presents three important diagnostic features, to wit: (1) Sudden appearance and very rapid growth, with intense pain and tenderness. (2) A rather extensive periglandular, brawny edema, which, with the firmly embedded, immovable lymph nodes, constitute a subcutaneous exudative mass without, as a general rule, any explanatory lesion of the cutaneous lymph-shed, and, on the whole, appearing to have resulted from invasion through the blood-vessels, instead of through the lymphatic vessels. (3) In case a point of infection is pressent, the induration about it is limited thereto, and does not constitute a part of the brawny edema of the bubo proper, with which it may or may not be connected by demonstrable lymphangitis. The extent of the periglandular edema in the case of large cervical bubo, with mucosal infection-atria in the pharynx, is particularly well marked. In addition to that, subcutaneously, there is a serogelatinous edema of the faucial pillars, uvula, and epiglottis. And it is of diagnostic importance in such large buboes that the pharyngeal tonsils are but moderately enlarged, while the lingual tonsils are strikingly swollen, and especially so in the absence of distinctive evidence of diphtheria, scarlet fever, or acute leukemia, with virulent sore throat.

Venereal buboes, involving the perpendicular and transverse inguinal nodes, and without demonstrable portals of infection, as a deep urethritis without meatal discharge, may be quite large and attended with fever and depression, but the surrounding edema is altogether disproportionate and incomparable in extent to that which would occur in a plague bubo of equal size, age, and rapidity of growth. The venereal bubo mounts up like a peak, while the plague bubo spreads out like a gradually sloping mound. The plague bubo is a large "cakey" swelling, the venereal, a lump. But in size and shape some plague buboes very closely resemble the ordinary venereal bubo.

In the septicemic variety the coexistence of the facies, tongue, and severity of attack, especially if the onset was with diarrhea and intense frontal headache, with injected conjunctivæ, justifies the provisional diagnosis of plague. But diarrhea and vomiting are, as a rule, the initial symptoms in all varieties. The one additional sign in the pneumonic variety is the sputum, which is tenacious and shows areas of blood, and not mere streaks as in lobar pneumonia, and which contains a greater percentage of blood than the sputum of that disease does.

In the diagnosis of plague by clinical signs it is important to bear in mind (1) that while the local pain and tenderness of a bubo is at first very intense, it gradually subsides, so that there may be found a typical anatomical bubo that is not painful or tender; (2) that persons desiring to deceive may deny having had pain or tenderness at any time, and sometimes they deliberately will bear firm pressure on the bubo for the purpose of misleading the clinician: (3) that the normal tongues of Asiatics frequently have a light brown coating, not to be confused with the wet, mahogany-brown coating of plague; (4) that the mortality statistics of venereal and other coccal buboes, compared with those of plague buboes, are indicative.

Clinical Microscopy and Cultures.—It should be borne in mind that the typically plump, bipolar *B. pestis* varies in shape and size, appearing as a small diplococcoid bacillus, or a bipolar rod larger than its usual size; also as a doughnut or lanceolate-shaped body or as a straight, uniformly stained bacillus. Bruno Galli Valerio has reported many variations, especially in cultures, and I have observed the disintegrated bacilli appearing as bacterial dust, as it were. Staining with toluidin blue colors the bacterial dust purple, and I am sure that the "dust" is not precipitated stain or cellular detritus. Material for smears and cultures may be obtained from a bubo by extirpating a portion of a node, or by aspirating a node with a hypodermic or larger needle, or by knife puncture and the use of the platinum loop. The material spread on a slide and flame-fixed may be well stained with a 2 per cent. toluidin blue in 1 to 2 per cent. aqueous solution of carbolic acid, allowing the dye to act for 15 to 30 seconds, and then rinsing in cold water. Pestlike organisms and others not taking Gram's stain, so far as I have examined, appear distinctly purple, while the Gram-staining organisms appear deep blue. A field laden with purple-stained bacteria or bacterial dust is extremely suggestive, the very presence of myriads of Gram-decolorizing organisms being indicative, even though they may be coccoid, lanceolate, doughnut-shaped, or otherwise pleomorphic.

Smears from some buboes may reveal no bacteria at all, but the bacterial dust usually is demonstrable. This condition may obtain postmortem, even though the spleen smears show numerous bacilli. From such buboes it is very necessary to make at least six agar cultures, incubating them at different temperatures, not being misled if the first colonies are cocci, for even after the fourth day the plague bacilli may appear, and perhaps in only two or three of the tubes. If bubo smears show bacilli two agar cultures will suffice, but otherwise make at least six, incubating in either case some at from 22° C. to 30° C., and others at 37°C.

In examining blood allow the unsmeared drop to air-dry, and then wash out the hemoglobin with normal saline, and stain the residue with toluidin blue. By this method easy demonstration of bacillemia is easy, for four or five such blood-drops may be prepared and examined without difficulty.

Blood-smeared agar-cultures are the best, incubating at different temperatures. In examining sputum and other mucous media, thionin (Berliner Actien Gesellschaft, and not the polychromatic dye of Grübler) is perhaps a better stain than toluidin blue, using the same mordant. Both stains are valuable on account of their avidity for mucin, in which *B. pestis* appears to be rich. The smears and cultures are best made from the blood areas in the sputum. As the sputum is likely to contain cocci, it is well to work gelatin-slant cultures and low-

temperature incubation with prompt subculturing. Agar, however, will answer if the cultures are incubated at low temperature—22°C. to 25° C.

Ordinarily, strepto- and pneumococci are present in sputum, and the plague bacilli at first may be few, while the cocci are numerous, and the sputum may contain bipolar Gram-decolorizing bacilli that are not pest organisms, as the pneumobacillus and others that have been found in rare hemorrhagic infections of man.

I recall the case of a farmer who, from physical signs, had lobular pneumonia, and the facies, tongue, and sputum of plague. To my surprise the sputum contained myriads of pneumococci (Gram) and only a few pest-like bacilli. Two hours later fresh sputum showed a slight increase in the percentage of bacilli. After another period of two hours I again found the bacilli increasing and the cocci apparently decreasing, though still plentiful. Four hours later, and about half an hour before death, the sputum showed a distinct predominance of pest bacilli and a striking diminution of cocci; and at necropsy, about eighteen hours after my first examination, and thirty hours after the onset, the patches of bronchopneumonia showed innumerable bacilli and but few cocci.

Symbiotically, *B. pestis* is more active than the pneumococcus, and the possibility of bacterial succession should be considered in the question both of pneumonic plague and of other rapidly fatal pneumonias. Be not misled if your first smears and cultures from sputum tend strongly to indicate a pneumo- or streptococcal infection only. And the same may again be said respecting bubo smears and cultures. Sputum should always be examined when fresh, for the *B. pestis* rapidly changes its characteristic form in that medium.

In the examination of feces, which offers a good chance for early diagnosis, and which should be made in every case, it is best to study well the Gram-stained slides, for many plump organisms which, if stained otherwise might show confusing bipolarity, discriminatingly will retain the gentian violet, while the pest bacilli will be stained well by the rosin used in the counter-staining.

The clinical microscopy of pest buboes will sometimes reveal the entire absence of bacilli, or even bacterial dust, especially in Yersin-serum-treated cases, while rarely only a few Gram-staining diplococci will be seen; yet the noticeable presence of most cells would be very suggestive. In some cases the bacilli do not appear in smears until true suppuration of the bubo ensues, while in others they will entirely disappear from slides when the purulent condition begins.

In foaming carcasses, due to the *B. aerogenes capsulatus,* and in those overrun by colon organisms, the pest bacilli are likely to be in the very insignificant minority. And such cases must be entrusted to inoculative and cultural methods.

Pathological Diagnosis.—The plague bubo presents only the attributes of an acute, rapidly developing, virulent process, noticeably and extensively involving, not only the lymph nodes, but the surrounding connective and muscular tissues as well. There is no evidence of, or tendency to chronicity, nor disposition of the process to limit itself chiefly to the lymph nodes, as is the case in coccal buboes.

Upon section plague nodes exhibit a distinct tendency toward hemorrhage, necrosis, and uniform consistency, while the surrounding tissues show a marked tendency to serohemorrhagic exudation, with but little inflammatory redness. The very succulent nodes do not tend toward true suppurative, but toward mere necrosis-liquefaction.

On section of a gono-, strepto-, staphylo-, or diplococcal bubo, the tendencies toward hemorrhage, uniform necrosis, and consistency appear wanting, while the disposition to suppurate is evident. The periglandular tissues, too, show no distinct and active tendency to exudation or hemorrhagic involvement unless associated with diphtheria, scarlet fever, or measles, when the throat and skin lesions are indicative. There is a marked inflammatory redness of the connective tissue immediately adjacent to the affected nodes, but the deeper muscular tissues are not edematous or otherwise especially involved. Plague inflammation is decidedly wet, while coccal inflammation is but moist.

In anthrax, acute glanders, and malignant edema, the lesions particularly involve the skin or mucosa and the contiguous soft parts, instead of, as in plague, exhibiting particular and essential attack of the lymph nodes and subcutaneous tissues—nor is the hemorrhagic tendency so marked as in plague.

The lymphadenitis of tuberculosis, syphilis, and leukemia does not similate plague nodes, except, perchance, the very rare and virulent acute types. In San Francisco I examined two cases of leukemia, one at the U. S. Marine Hospital, the other at St. Luke's, in which the tissues fairly suggested the possibility of plague. In the St. Luke's case there was a diffuse, moist, retroperitoneal hemorrhage about the iliac and lumbar nodes, which, in extent and location, was very comparable to the hemorrhagic periglandular edema of plague. It was, however, but moist and not wet, as in plague, nor were the psoas and iliac muscles edematous. The iliac and lumbar nodes, while hemorrhagic and much softer than the characteristic leukemic nodes elsewhere in the body, were not succulent or of a uniform consistency at all approaching that of a plague node. And further, the cellular and bacterial evidence indicated leukemia.

In the Marine Hospital case, which was characterized clinically by acute onset with fever, gangrenous pharyngolaryngitis, large and tender cervical lymphadenitis, and hematuria, the post-mortem showed that the cervical lymph nodes, while acutely hemorrhagic, revealed their chronicity in the consistency so like that of the leukemic nodes elsewhere. And the surrounding edema, neither in extent nor kind, was similar to that which invariably would attend a plague bubo of equal age and size. The kidneys and bladder were markedly hemorrhagic, and many is particularly true in rat-examinations.

The lesions of a typical plague bubo-chain are quite as characteristic and definite of pest infection as are tubercles and cavities of phthisis, and in the great majority of cases bacteriological confirmation for diagnostic purposes is no more called for than it would be in typical tuberculosis. But in many other cases of plague the diagnosis can be made only by bacteriological methods, and the *B. pestis* cannot be recognized by mere clinical microscopy. This is particularly true in rat-examinations.

Bacteriological Diagnosis.—The most troublesome associates of *B. pestis* are the colon-group organisms. In case the primary cultures are overrun with such bacteria, attempts at plating or rapid subculturing, even at low temperatures and on special media, will prove tedious and unsatisfactory. The most serviceable method is to filter out the colon bacilli by cutaneous inoculation of a guinea-pig's shaven abdominal wall. The tissue or culture should be rubbed on an area about 2 cm. in diameter, without breaking the skin. Post-mortem cultures from this pig's spleen or heart's blood usually will be free from colon and other bacteria, such as pneumococci and streptococci, provided the animal is examined

promptly. And it is well to chloroform the pig when the natural outcome appears inevitable, in order to avoid the chances of agonal invasion of undesired organisms.

But if the colon persist, as may be suggested by the bacterial morphology of the smears, a second guinea-pig should be similarly inoculated with the spleen of the first. If only cocci persist, prompt subculturing on gelatin or agar and incubating at from 22° C. to 25° C., nearly always will cause their total, or at least apparent, eradication.

In post-mortem and clinical work it is always advisable to inoculate several slant agar tubes, a guinea-pig cutaneously, and a rat subcutaneously with emulsion or bits of tissue. Sawdust, frequently kept in cages, will in time cause nephritis in rats, and such renders them unfit for use, for invariably they will die of toxemic pest. Some of the agar cultures should be incubated at from 22° C. to 25° C., and subcultures promptly made, if cocci are demonstrable by Gram's or Cladius' methods; others, at 37° C., because pest at one time may not grow promptly at a temperature below 30° C., and at another time not at a temperature above 30° C.

If the primary cultures should be overrun by colon bacteria, await the results of animal inoculations, and then obtain a new set of cultures. In recovering the bacillus from putrid tissues it is well to emulsify a bit, and give the centrifugally collected sediment two washings in bouillon, preparatory to cutaneous inoculation of the guinea-pig.

If after 48 hours' cultivation only bacilli appear that are morphologically and tinctorially pest-like, particularly if the colonies exhibit moderate viscosity, the probability is that the culture is pure. To test the purity of this culture, and at the same time to determine whether the bacillus, biochemically and culturally, is *B. pestis,* inoculate two bouillon tubes, incubating the one at from 25° C. to 30° C., to develop the rather characteristic pest growth, and the other at 37° C., to determine whether cocci are present, for sometimes they seemingly disappear from agar cultures, but show themselves when given a more favorable medium and temperature. Without waiting for this coccal test inoculate plain and litmus milk, peptone solution, and sugar media, either solid or liquid, and incubate until active bacterial growth develops. Gelatin stabs also may be made and incubated at low temperature, in order to compare the development with the pneumobacillus in gelatin stabs. *B. pestis* does not produce demonstrable change in plain milk even after two weeks' growth, while the somewhat pathogenically similar *B. pseudotuberculosis rodentium* coagulates it, as does the pneumococcus, as a rule, but not always. In litmus milk, pest causes a *very faint,* barely appreciable, acid reaction, up to the tenth or fourteenth day, and in Dunham's peptone solution it, at times, produces indol. The indol reaction is faint, but present, especially if the organism has been kept long, or rapidly subcultured on agar. It does not ferment sugars, liquefy gelatin, or require hemoglobin for its development. Its growth in bouillon is indicative, forming very characteristic stalactite growths and floating flakes made up of streptobacilli of typical pest-like morphological and staining qualities. This is best developed at about 25° C., taking due care not to slake down the hanging flakes by jarring the tube. At 37° C. the bouillon is more apt to appear cloudy and settle more quickly to the bottom, forming a mucinoid sediment, that, by circularly shaking the tube, may be made to rise up through the bouillon in a viscid column. As far as my work has progressed in the cultivation of the *B. pestis* in antitoxic serum, I am inclined to consider of diagnostic value the resulting well-formed, compact chains composed of six or eight plump bacilli showing typical bipolarity and decolorizing by Gram's method.

If, then, this morphologically and tinctorially pest-like bacillus, taken from agar colonies of pest-like viscosity, grows in the several special media as *B. pestis* is known to do, it may be fairly regarded as culturally and biochemically *B. pestis.* Its pathogenicity, however, must be demonstrated, for culturally *B. typhosus* not only parallels it in those media and on potato, but reacts similarly to Gram's stain and at times may show polar staining, and the toxin-forming aspects of the two bacilli are similar. The bacillus of swine plague and the bacillus of chicken cholera also simulate its cultural, morphological and tinctorial features in many respects, while the *B. pseudotuberculosis rodentium,* very virulent influenza, and colon bacilli, may produce comparable lesions in animals, and possibly in man.

The inoculation then with the pure culture should be made intraperitoneally in a guinea-pig, using a few drops of a 24- to 48-hour-old bouillon culture. At the same time a rat may be subcutaneously inoculated to differentiate pathogenically *B. pseudotuberculosis rodentium,* and a pigeon subcutaneously or intramuscularly to exclude further the numerous other organisms of the hemorrhagic bacteriemias of lower animals and poultry. If the bacillus is that of bubonic plague, the necropsied guinea-pig will exhibit a copious, very ropy, grayish peritoneal exudate unmixed with blood, but extremely rich in like bacilli; also bacillemia and numerous miliary nodules in the spleen. Dermic pure-culture inoculation of a guinea-pig, will cause hemorrhagico-necrotic lymph nodes and an infection-atrium comparable to those in the primary or tissue-inoculated guinea-pig. And so with the rat and with the rabbit, should pathogenic differentiation of the pneumo-bacillus be sought. The pigeon will remain alive and well if subcutaneously or intramuscularly inoculated, but pest-infection by feeding may prove fatal.

Another test is that in pregnant animals and women the *B. pestis* does not pass through the placenta and enter the fetus, or at least it cannot be demonstrated in fetal tissues, thus differing from *B. typhosus,* the bacillus of swine plague and the bacillus of chicken cholera. Use also may be made of experimental immunization of animals to plague, followed by inoculation of the pathogenic bacillus in question. And it is likely that definite differention will soon be practicable through agglutinins, precipitins, and other derivatives of biochemical products.

In testing the pathogenicity of a pest-like bacillus, it is very important to bear in mind the fact that *B. pestis* at times becomes so attenuated that its pathogenic property is almost inappreciable. Whenever a culturally pest-like bacillus proves non-pathogenic, it should be carried through the collodion-sac or other methods calculated to increase its virulence, and then further inoculations with young cultures made, using young guinea-pigs. Widal's reaction will promptly differentiate *B. typhosus,* and within certain limits other bacilli.

Epidemiology.—*Host and Distributors of the Infection.* — A. Insects.—(1) Special-Diet or Suctorial Insects.—Mosquitos, lice, bedbugs, ticks, and fleas may obtain the contagium by sucking the blood of bacillemic persons, rats, and other animals, and their bodies also may possibly become contaminated

by contact with infected material. Such insects may distribute the infection, mechanically, by their feet, and when crushed upon the skin or clothing. The well-founded conclusions of Mühling and Nuttal indicate that insects do not, by biting, inoculate bacteria, either when infected themselves or when the part to be bitten has been smeared with bacteria. Plague inoculation by flea-bites is highly improbable, and the chief danger of human and animal infection from suctorial insects is when one crushes them on the skin, or in the mouth as animals are wont to do and as some Chinese do fleas. The reason why such insects do not inoculate bacterial, as well as protozoal diseases like malaria, Texas fever, mountain or tick fever, is of course due to the fact that bacteria do not reach their injecting salivary glands. (2) Omnivorous or Scavenger Insects.—Flies, cockroaches, and ants obtain the contagium by feeding and by resting on infected material, such as foods, sick and dead persons and animals, sputum, feces, moist soil, etc. As distributors, their feet and excrement are ready agents with which they contaminate wearing apparel, bath-tubs, towels, floor-dirt, kitchen tables, eating utensils, solid and liquid foods, sweets and other eatables of street vendors, and many other things from which cutaneous and alimentary tract infection would likely result. In other words, they obtain and distribute pest contagium, as they do the organisms of cholera, enteric fever, anthrax, and ophthalmia. Ants take their infected cargo from foods and dead insects, and it is obvious how readily they could distribute it to floor-dirt, tables, etc. (3) Granary Insects.—It is possible that these may become infected from rat dejecta on grain, and that they may retain the infection in grain transported from one place to another, and of themselves be a source of infection to poultry and animals feeding on such grain.

B. Animals, Poultry, and Man.—(1) Rats contract plague (a) by eating and drinking infected foods; (b) by licking one another, as well as their own feet and bodies that have been in contact with infected material such as human sputum on sick-room floors, and human feces in sewers; (c) by biting and crushing infected fleas, and possibly by inoculation of cutaneous abrasions, but very improbably from flea-bites. (2) Other animals, like cats, dogs, swine, sheep, and cattle, as well as poultry and birds contract and distribute the disease similarly. (3) Man contracts the disease (a) by eating the insufficiently cooked flesh and viscera of infected animals and poultry; (b) by eating and drinking foods that have been infected by insects and rats, or by contact with infected hands, dishes, and tables; (c) by cutaneous inoculations—*B. pestis* may reach the skin as the pyogenic bacteria do, and, like them, be rubbed into abrasions, hair, and sebaceous follicles by the clothing; (d) by pulmonary infection from aspiration of bacilli from a primary throat lesion, and very probably by hematogenous invasion. Neisser and others duly conclude that infection by breathing dusty air is altogether unlikely. There are many facts pointing to the alimentary mucosa as the principal and original channel of infection, and I have found it well always to attach special importance to the lingual and pharyngeal tonsils and the gastroduodenal mucosa, in connection with the question of hematogenous origin of subcutaneous buboes, and invariably in the clinically "septicemic cases."

C. Fish, crabs, and oysters are apt to feed on infected foods, sewerage, and dead animals entering waters frequented by them, and when marketed, they may become a very common source of infection to raw fish-eating people, and to flies, poultry, and rats, as well as kitchen utensils, etc.

D. Experimental Viability of *B. pestis.*—Rosenau concludes: (1) *B. pestis* is not a frail organism. It resembles the hemorrhagic septicemic group or the coccobacilli as far as its viability is concerned. (2) Temperature is the most important factor in the viability of the *B. pestis.* It keeps alive in the cold, under 19° C., a very long time. It dies quickly, especially when dried, at 37° C. (3) Moisture favors the life of the bacillus. It usually dies in a few days when dry, even in the presence of albuminous matter, provided the temperature is above 30° C. It may keep alive and virulent when dry, for months, in the cold, under 19° C. (4) Sunlight kills the organism within a few hours, provided the sun shines directly upon the organism and the temperature in the sun is over 30° C. The effect of sunlight is not very penetrating. (5) The virulence of the bacillus is often lost before its vegetative powers. (6) It is unlikely that new merchandise would carry the infection. The organism usually dies in a few days on the surface of objects, such as wood, sawdust, bone, paper, etc. (7) Clothing and bedding can harbor the infection for a long time. The bacillus lives for months, when dry, in albuminous media at temperatures under 20° C. (8) The bacillus lives a long time in milk, cheese, butter, and water. It usually dies quickly on the surface of fruits and prepared foods. (9) In sterilized garden soil containing moist albuminous matter (bouillon) at 37° C., the bacillus lived 14 days, while at cooler temperatures, 17° C. to 19° C., it lived from 84 to 93 days."

It is noteworthy that suctorial insects derive most of their infection from bacillemic victims; that they do not by biting inoculate bacteria, and that rat fleas are not wont to infest man; that plague rats must therefore be dangerous chiefly by distributing their dejecta to the foods and habitations of man, animals, poultry, and insects; that scavenger insects are particularly exposed to the contagion distributed by rats, animals, fish, man, and other agents, and that they are well qualified for distributing the bacilli to human foods and habitations; that suctorial insects and rats of all ages and susceptibilities unrestrictedly continue active throughout the year, while scavenger insects are particularly active during the seasonal prevalence of plague, and likewise inactive during the seasonal lull; that the foods, environments, and habits of suctorial insects and rats are not essentially altered during the year, and that at all times they have the same capabilities of conveying bacteria to one another and to man.

Experimentally, the *B. pestis* may become attenuated by successive passage through rats, and this fact has been offered in explanation of chronic rat plague, which is characterized by cervical lymphadenitis without bacillemia, and which, it is said, supersedes the acute or bacillemic type periodically, and especially prevails during the seasonal lull in the rat and human plague *deaths;* and further that the seasonal abatements of the epidemics occur, because these chronic or non-bacillemic rats are incapable of infecting one another and man, either through the agencies of their fleas or their dejecta, but that the new generations of rats, being young and therefore very susceptible, develop the bacillemic type, and so opportunely distribute the bacilli that the seasonal recrudescence of human and acute rat plague takes place. In this connection, however, it is to be noted (1) that rats breed 4 or 5 times annually, and that the young rats at the age of about 6 months begin to breed, so that there is throughout

the year an ample supply of rats of all ages and susceptibilities; (2) that the coming of the new generations of rats is not an annual event, as is the rise in the epidemic curve; (3) that the temperature and humidity preceding and during the lull are not such as would, of themselves, diminish the virulence or viability of the bacillus. It appears to me that there is an ample supply of susceptible persons, rats, and fleas, throughout the year; that if the bacilli were obtainable, the human and rat epidemics would keep up; that the rise and fall in the human epidemic is not dependent on the rise and fall of the rat epidemic, but that a seasonal variation in the distribution of the bacillus is the common cause of the fluctuations in both epidemics, and that the omnivorous insects, particularly flies, cockroaches, and ants, are largely responsible for such seasonal variation.

Rat plague abates (1) because the scavenger insects become inactive with the natural close of their season, or from their diminution by heavy winds and rains, which also remove many of their breeding places and infection sources on the ground surface and in sewers; (2) because rats migrate and shun suspicious food, whenever there occurs among them an epidemic sickness caused either by chemical poisons or by bacteria, and so the total number likely to be exposed to infected sources is reduced.

Human plague abates, not as a result of the rat plague abatement, but because the scavenger insects less extensively infest and contaminate wearing apparel, human foods, and habitations.

Herein, I think, lies the principal factor in the rise and fall of the human and rat epidemics, and the essential indication for the eradication of the disease.

In the eradication of plague, the "usual measures" have not been entirely satisfactory, and I believe that it is necessary to kill scavenger insects as well as rats, and the latter not by the remarkably limited means of poisons and traps. They should be shut off from human habitations and from their other food-sources, breeding-places, and haunts by screening doors and windows, and closing the cracks and holes in food markets, houses, stables, abattoirs, etc. Further measures of prevention consist in prompt and thorough removal of street droppings, garbage, sewerage, patches of moist albumin-containing soil, back-alley and vacant lot feces, and other accumulations, and in paying due attention to the industry of marketing fish and crabs from waters likely to be contaminated by infected sewerage, dead rats, etc., and also to the marketing of animals and poultry likely to suffer with subacute and chronic plague.

Transmission of the Infection from One Place to Another.—In this connection the epidemics of Hawaii and of California are especially indicative. The original focus of infection in Hawaii was Chinatown, Honolulu, which is quite removed from the docks. In California, the original focus was Chinatown, San Francisco, which likewise is well removed from the docks. In both instances, the disease began in the Chinese quarters and spread thence to other sections of the cities, and in Hawaii from the Island of Oahu to other Islands of the group, and in California from San Francisco to Oakland, Pacheco, Concord, and other interior places. In neither case does it appear at all probable that infected ship rats were carted into those districts along with cargo. And even though alien plague rats should effect a landing, and an epidemic among the wharf rats and laborers ensue, it must be borne in mind that infected foods, cockroaches, and articles landed from the ships, would also infect the wharf rats, insects, and laborers, and the fish and crab thereabout. Plague-infected cockroaches and granary insects are more likely to be imported in cargo and baggage, and to be carted away to distant parts of a city, than are plague-infected rats. And the rôle of infected persons is obvious, for their dejecta and sputum are dangerous to scavenger insects and to rats infesting sewers.

The principal transmitters of infection from port to port are (1) imports likely to be eaten or infested by insects and rats; (2) persons, wearing apparel, and bedding; (3) scavenger, and possibly, granary insects; (4) rats and other animals.

THE LIMITATIONS OF THE OFFICE TREATMENT OF RECTAL DISEASES.

BY CHARLES B. KELSEY, M.D.,
NEW YORK.

SOME eight years ago the writer published a small book on "The Office Treatment of Hemorrhoids, Fistula, etc., without Operation," which some of my fellow members of this society may have seen. It was stated in it that "a very large proportion of all cases of piles, fissures, superficial ulcers, and pruritus, and a certain proportion of abscesses and fistulæ may be radically cured in one's office without resorting to ether or confinement to bed." Also it was stated that "the methods by which these results may be accomplished do not include any new surgical principle, but simply the application of modern methods more effectively and perhaps with greater ingenuity. These methods have, it may be said, been floating through surgical literature for years, but have received only temporary and casual

* Read before the Medical Society of the County of New York at a meeting held December 27, 1904.

attention. No man seems to have deliberately tried them to their full efficiency as a rule of practice, before resorting to the better known and generally accepted operations under anesthesia."

My reason for including piles in this category was that at that time I was having considerable success with experiments in the old French treatment by punctate cauterization modified by the use of cocaine instead of general anesthesia—a treatment thoroughly aseptic in itself, attended by no hemorrhage at the time or after, and seldom causing sufficient after-pain to confine a patient to the house. These experiments have never been published because after years of trial the method does not appeal to me as a safe one for recommendation to the general practitioner, however well it may work in selected cases in the hands of one with sufficient experience to know when and how to employ it. The little book was therefore after two or three editions allowed to drop out of print, and I only refer to it now to explain that in saying the majority of cases of piles could be cured in one's office without general anesthesia or confinement to the house, I did not refer to a cure by either the ligature or clamp operations.

It thus happens that after eight years of constant use in my office of local instead of general anesthesia in selected cases, when we come to discuss the limitations and applicability of these methods, I cannot do better than repeat what I then said with the addition of this explanation, viz., that "a very large proportion of all cases of piles, fissures, superficial ulcers, and pruritus, and a certain proportion of abscesses and fistulæ, *may be* radically cured in one's office without resorting to ether or confinement to bed."

Experience has not led me to increase this list of diseases, and we may to-night analyze even these very closely in our discussion of the limitations of office treatment.

Take in the first place hemorrhoids. The worse the case the better is it adapted for the easy application of local anesthesia. Nothing is simpler than to inject a large prolapsing internal hemorrhoid with cocaine, eucaine, or water (I prefer eucaine), throw a ligature around it and cut it off. Much simpler is this than to get above the sphincter and operate through a speculum upon piles which though requiring operation never prolapse, though they may cause every other symptom except prolapse. For our purpose now all hemorrhoids may be grouped under three general clinical forms—the thrombolic, the distinctly prolapsing, which can be caught and treated when prolapsed, and the equally severe cases which, though causing tumefaction of the anus in straining, and requiring for their cure an incision at the mucocutaneous junction, still never prolapse.

My own experience with local anesthesia has convinced me: (1) That to place an hypodermic injection into a thrombolic pile before turning out the clot is not as painful as turning out the clot without the anesthetic, and is therefore a distinct gain.

(2) That prolapsing hemorrhoids may be satisfactorily operated upon by several methods, the best of which for general use is the ligature. The ligature is much better adapted for local anesthesia than the clamp for the reason that the pile itself is easily rendered painless; but the suffering caused by a powerful clamp in a strong right hand, even when applied to a pile itself dead to pain, may be unendurable. I have known a man suffer agony from the clamp who did not even feel the cautery, because the effect of the latter was confined to the anesthetized spot, while the former causes a squeezing, dragging pain on all the surrounding tissues in no wise lessened by the cocaine in the pile itself.

(3) That to attempt to dilate the sphincter, use a speculum, go up into the rectum proper and operate upon three or four piles which do not prolapse, as such cases should be operated upon, first by thorough dilatation of the sphincter, then by an incision at the mucocutaneous junction, followed by the clamp or ligature requires such a quantity of the local anesthetic introduced at so many different points of the most sensitive parts of the body as renders the method exceedingly unsatisfactory and general anesthesia far preferable.

(4) In the treatment of fissures by stretching, local hypodermic anesthesia is not applicable, although most satisfactory in the treatment by incision.

(5) In superficial ulcers, cocaine or eucaine applied on cotton works as well as in the nose and throat.

(6) In pruritus, where the use of the cautery is indicated, hypodermic anesthesia is very satisfactory; and small abscesses and fistulæ may also be operated upon in this way in the office. As for attempting to operate upon large abcesses or anything but the shortest and straightest fistulous tract with local anesthesia in my office, it would never occur to me, for the simple reason that in severe cases one never knows how much cutting will be necessary, and a half hour's quiet dissection is by no means unusual in my own practice. For this kind of work local anesthesia would not seem well adapted.

It will be noticed that in thus briefly enumerating the class of cases in which hypodermic anesthesia is best adapted we are keeping very closely to those in which the agent used can be placed in a circumscribed area and exactly where it is wanted. To attempt to anesthetize the whole anal and lower rectal region by hypodermics of cocaine or eucaine is dangerous from the constitutional effects of the drug; and with water it is either ineffectual or causes great pain and tumefaction. The nerve-supply which must be affected is very generous and comes from several branches on each side, all of which must be reached. This method is therefore inapplicable to extensive disease.

Again, the giving of ten or twenty hypodermics in this region is much more unpleasant than general anesthesia.

Having thus briefly enumerated the class of cases to which local anesthesia is best adapted, we may consider as briefly the limits to which office operating should be carried.

Because an operation may be done painlessly, it does not follow there will be no subsequent shock or suffering. A man may nerve himself to undergo an operation for piles with local anesthesia in the office, and at the time suffer little. Still there is generally some nervous shock, often a good deal, and after a few minutes the pain will begin and he may be very glad to get home and abed and stay there several days. I have found no advantages in operating by the ligature in my office, putting the patient in a cab and sending him home, going there after him in an hour to give him morphine, and tending him for a week, over the more usual custom of going to his home to operate in the first place. In fact, there are many disadvantages, and the question of asepsis comes in very prominently, for a doctor's working office and examining table are never aseptic and cannot be; and the injection of a sterile solution into the substance of a pile by no means constitutes asepsis in the subsequent cutting operation for the removal of that pile. It is hard to find

any procedure less aseptic than the puncture of the gut with a hypodermic needle from within the caliber outward—a procedure which has itself been fatal from general septic poisoning, as notably in the recent case seen by me and others in consultation. The technique is essentially the same as sewing the opened gut to the abdominal wall, by passing the sutures from the caliber outwards, which is known to be extremely dangerous, no matter how sterile the needle and suture may be. It may be, as I believe, that the mucous membrane of the gut is never absolutely sterile and cannot be made so by any practical means, but this is no excuse for neglecting any precaution to make our operations as aseptic as possible; it is, in fact, an excellent reason for doubling the precaution.

In a general way I think it may be stated that any cutting operation for hemorrhoids is a matter of some seriousness; that it is often attended by considerable shock; that it is apt to be bloody and should be done with as perfect asepsis as possible; and that whether done by local or general anesthesia, at the office, home or hospital, the patient is better off resting quietly in the house for a few days after. I am aware that some men will undergo this operation and get up and go about their usual business. They are not the majority, and it does not prove good surgery that even a few may be able to do it. To me this is a question not of personal preference on the part of the surgeon as to where he shall operate, but of safe and cautious surgical practice by which the patient is subjected to no unnecessary risks and is made as comfortable as possible.

For these reasons, when I operate upon suitable cases of piles with local anesthesia, I much prefer to operate at the patient's home or hospital rather than in my office on my examining table, and to use the same precautions and give the same subsequent care he would have were the anesthesia general instead of local. The amount of this care will depend upon the disease and the individual, but is usually more than is compatible with free exercise and attention to business, though it may not be necessary to stay in bed and have a trained nurse. If the patient is led to suppose he will have no suffering and need only report in a week, there is apt to be bitter disappointment.

In short, neither the surgery of the rectum or the after effects of such surgery are in any way greatly changed by the substitution of local for general anesthesia, unless the attempt to obtain local anesthesia be carried to extremes, and additional suffering and other complications are thus produced, as sometimes may happen. For the mere production of local anesthesia by hypodermic injections into this part is very painful, and when the injections are numerous and the amount of fluid large the local edema and swelling must be counted on, often as a very troublesome complication.

There is one other question which I would put, merely in the form of a suggestion.

Is it best for the patients that general practitioners all over the country should be taught that aseptic precautions at the time and rest at least at home for a few days after operations of this kind is an exploded antiquated notion? That all that is necessary is to inject some sort of sterile anesthetic into the piles or fistula, operate, and tell the patient to go on about his business regardless of the risks of pain, hemorrhage, retention of urine, and all the other possibilities attendant upon these operations? Is not a method which is applicable to a few of the simpler forms of disease being unduly magnified, and will not accidents surely follow? Do we not thus belittle the importance of a class of operations in themselves neither little, unimportant, or free from danger?

There is no doubt that many patients are now, as in the past, subjected to the trouble, expense, and confinement attendant upon general anesthesia for very trivial affections which could easily be operated upon with a few drops of cocaine in the office. Also, there is no doubt in my own mind that to attempt to reduce the majority of the surgery of the rectum to these simple proportions will result disastrously.

18 East Twenty-Ninth Street.

THE USE AND ABUSE OF CURETTAGE OF THE UTERUS.*

By E. K. BROWD, M.D.,
NEW YORK,
ATTENDING GYNECOLOGIST TO ST. MARK'S HOSPITAL; ASSISTANT ATTENDING GYNECOLOGIST TO THE GERMAN POLYCLINIC.

Curettage of the uterus is the simplest of all gynecological operations. It is used, according to Howard Kelly, to remove the superficial portions of the uterine mucosa in endometritis, to secure bits of tissue for diagnostic purposes, in suspected cancer of the body, and to remove portions of the incompletely cast-off ovum. In private every-day practice, curettage has occupied a still larger field, and has been used rather extensively whenever a mere suspicion of an existing uterine lesion was present.

Curettage is largely known among the lay community as "the cleaning of the womb," and is believed by them to be a panacea for all sorts of menorrhagias, metrorrhagias, and leucorrhœas. The uterus, as a rule, is regarded to be the offending organ. A little closer study into the pathology of the generative organs brings forth the conclusion that there may exist similar morbid manifestations springing from two entirely different sources. Thus a hidden tubal pregnancy may produce intrauterine oozing which cannot be removed by curettage; a case of long-standing sterility, with diseased adnexa as a cause, may resist the most ardent attempts at divulsion and scraping of the uterus. The uterine appendages, which play such an important functional rôle, have been frequently lost sight of, and a close microscopical examination of the endometrium is often overlooked. Whenever there has been observed a sanguineous, semisanguineous, or leucorrhœal discharge from the os—there has been a great tendency to enter the first door to the disease, the endometrium—the scraping has been performed on general principles, and its use, therefore, frequently proved to be symptomatic. Again, "on general principles," cases of puerperal sepsis of different sorts and forms, puerperal endometritis, endometritis with existing pyosalpinx, be it acute or chronic, have been boldly attacked. The ease of technique of curettage, and the seeming absence of risk involved, may probably account for its indiscriminate and frequent use. It is the purpose of this paper to plead for a more reserved and cautious use of it, as my observation leads me to believe that this "home" operation has very often brought about great fatalities, which were the result, not so much of the faulty technique of the operator, as of the preexisting pathological lesions of the uterus or adnexa, which did not sanction the use of curettage.

Curetting is a most useful resource in cases of endometritis, not associated with pelvic inflammations or exudates or diseased adnexa; in cases of subinvolution of the uterus or retained secundines, post partum or post abortionem; endocervicitis as preventative against carcinoma, in mole pregnancies and in all cases of endometritis of so-called "hyperplastic" nature. Here curettage is useful, and many

* Read at the meeting of the Eastern Medical Society.

practitioners can cite cases of absolute cure. On the other hand, whenever with the above-mentioned conditions, the adnexa or pelvic cellular tissue are involved, its use becomes doubtful. One text-book, however (American Text-book of Gynecology), strongly and absolutely advises the use of a sharp curette in all cases of acute septic gonorrhœal endometritis, even in the case of acute tubal and peritoneal inflammations of uterine origin, in order to check the supply of septic material from the endometrium, and thus prevent an extensive infection of the tube and peritoneum.

Some gynecologists claim good results of curettage in cases of acute purulent salpingitis and peritonitis, even in cases of old endometritis with pyosalpinx, with expectation that osmosis through the uterus may deplete the infected Fallopian tube (Polk). Berlin of Nice curettes the uterus even when the adnexa are painful.

Some use the curette only in cases of endometritis, with catarrhal or interstitial salpingitis (Coe, Boldt), and warn us against it in both acute and chronic cases, on account of danger of reproducing an acute attack of tubal trouble, or causing an intraperitoneal rupture of the dormant pus tube. Others, again, treat all cases of septic or specific endometritis by curettage (Dudley, Krug).

It is quite a natural desire for a young practitioner to curette the uterus in a post-partum case, with a temperature of 102° to 103°, associated with chills, in order to remove the suspected focus of infection. While curettage is of greatest benefit in cases of putrid saprophytic infection, or sapremia due to retained secundines, it is proved to be harmful in cases of septicæmia due to pyogenic streptococcus infection. In the first case, the curette removes placental débris, and with it the saprophytes which thrive only on dead tissue; in the second case, curettage removes the infected ulcerated endometrium, and produces a new traumatism, opening the lymphatics for a new infection of the microorgainsms.

Kroenig (cited by Edgar) obtained by expectant and supporting measures without curettage, a mortality of only 4 per cent. in cases of streptococcus infection; 80 per cent. of patients with streptococcus infection recover spontaneously from the formation of a protected layer of leucocytes in the decidual lining of the uterus.

Whitridge Williams and Kroenig, appointed by the Commission of the American Gynecological Society, made an analysis of every case of puerperal fever reported in the literature of the world for five years. They found that curettage of the uterus, when bacteriological examinations have been made and streptococcus found, gave the frightful mortality of 22 per cent. They themselves applied no local treatment to the uterus whatsoever, and had a mortality of 5 per cent.

Pryor adopted the method of posterior cul de sac incision and packing with iodoform gauze in cases of streptococcus infection. He claims to have had no deaths except when he operated upon cases which were curetted before coming into his hands; out of ten such curetted patients he had a mortality of 33 1-3 per cent.

Reports of Bumm (Basler Frauenklinik) present the following: He had, post-partum, thirty-eight cases, out of which 20 cases ill-smelling, 18 cases bleeding. He used no curettage, and all his patients recovered. But of 13 cases curetted post-partum, 3 developed thrombotic phlebitis, 1 endocarditis, 1 parametritis, 1 perimetritis, and 1 died.

Dr. Riou (Jahresbericht Geburt. u. Gynäkologie) states that in the year 1901, in the clinic of Tarnier, with treatment by intrauterine irrigations or digital detachment of débris in puerperal fevers, post-abortionem or post-partum, he had a mortality of 0.057 per cent. It is, therefore, of vital interest to ascertain whether we are dealing with a case of sapræmia or streptococcus infection.

Our attention, then, is directed to a bacteriological examination of the uterine discharges, the result of which is to govern our treatment of the lying-in woman. However, according to Fehling (cited by Vineberg), a microscopical examination of uterine discharges cannot always be relied upon, as streptococci or staphylococci have been found in the discharges of normal uteri; and, on the other hand, in severe forms of puerperal infection, only occasionally streptococci, sometimes staphylococci or bacilli coli communis, or mixture of these, have been found. Neither could a bacteriological blood examination reveal the presence of pathogenic germs in the puerperal septic woman (Vineberg).

The treatment, therefore, is not always easy to determine, and must be based chiefly upon the clinical history; upon characteristics of pulse, temperature, and upon personal observation and experience.

According to the researches of Fritsch, in most cases of puerperal sepsis the endometrium is only secondarily affected; the infection generally proceeding from the cervix and its deep laceration into the parametrium, and he is therefore hostile to the intervention of the curette. In the same manner infection may travel up into the genital tract from a lacerated perineum or from injuries to the vagina or vestibule, caused by instruments, and produce elevation of temperature or pulse in the treatment of which curettage is contraindicated.

Curettage and divulsion constitute the routine treatment for sterility in a nulliparous woman; the condition of the ovaries and tubes and their importance in fecundation are not always considered. To emphasize the danger of invading the healthy endometrium by curettage, Dr. J. B. Cooke (*American Journal of Obstetrics*, 1904), mentions three cases in which ectopic gestation followed operations of curettage. Plastic operations upon the ovaries and tubes, excision of diseased parts thereof, and most remarkable ovarian graftings, have been successfully performed of late. The conservative surgeon finds favorable response in his most noble attempt to combat this woe of womanhood—sterility. Men like Polk, Ill of Baltimore, H. Kelly, Dudley, and others, are responsible for this good work. Exploratory laparotomy involves but little danger, while unnecessary curettage may aggravate pathological conditions.

Curettage has been frequently attempted in cases of old endometritis, with or without existing sterility, upon a retrodisplaced uterus, bound down by old adhesions, or in the presence of pelvic exudates. Here, the very traction of volsellum forceps, may injure old adhesions probably bound to the intestines and cause a fresh pelvic inflammation or pelviperitonitis.

Cases of syphilitic, tuberculous, sarcomatous, or cancerous degeneration of the endometrium, manifesting local symptoms of leucorrhœal or sanguineous discharges, have been also frequently doomed by curettage. It is in these cases that perforation of the brittle diseased endometrium is liable to take place.

Should microscopical examination of the endometrium reveal the presence of malignancy, a more radical treatment, say hysterectomy, should be instituted. Quite often a sanguineous discharge may mask and harbor an incipient cancer of the uterus, and the family physician cannot be too optimistic as to the results of curettage. Here the life of the

patient is in his hands; conservative curettage may delay a timely hysterectomy, which could save the patient from slow death.

This simple operation of curettage, which, according to the late Dr. Mundé, in his Manual on Minor Gynecology, could be easily performed in the physician's office, is quite frequently executed in the patient's bed, on an improvised Kelly's pad, without assistant or anæsthetic, as a satisfaction to the request of the nervous woman. Such procedures are associated with danger of perforation and, curettage should be done only when the parts are well exposed and non-resisting.

Case I.—Mrs. S., 26 years old, menstruation regular. No previous ailment; married three years; no children, no miscarriages. Applied for treatment of sterility. Divulsion and curettage advised by family physician. No anæsthetic given. When being curetted the woman gave a sudden jerk upward, coming down suddenly with her body, causing the curette to plunge into the uterus. No perforation was noticed the same day. Next day, while the gauze was being removed, a shiny mass of membrane was pulled down by the dressing forceps, and this turned out to be a part of the omentum and intestines. Packing of the uterus followed with transfer of the patient to the hospital. An anæsthetic given and laparotomy was performed; five inches of black congested gut were resected and Murphy's button was introduced. Lambert's sutures were applied and the uterine rent was closed. The woman did well for one week, then succumbed to septic peritonitis. This case shows plainly the danger of curettage without an anæsthetic.

Curettage presents danger and aggravates the already existing lesions, when performed in the midst of the septic surroundings of the tenement house, where the body, bed, or genitals cannot be rendered perfectly aseptic. I have seen pelvic abscesses following curettage, after a fresh non-septic case of abortion.

Case II.—Mrs. W., 24 years old. Had two children, no abortions. Regular menstruation. Always been well before. She suffered from retained menses for two weeks, then from bleeding. Temperature normal; pulse 78. The only existing symptom is bleeding, no pain. Curettage was performed at her home; two days after she had chills, fever, a temperature of 103°, and intense pain in the right inguinal region. Examination revealed a mass the size of a walnut in the right posterior cul de sac. Pain and fever continued for one week more, the tumor getting larger. An incision in the posterior cul de sac gave exit to bad-smelling pus. Drainage was instituted and recovery followed after a stay of six weeks in bed. The adnexa on the right side are still swollen; the uterus is non-movable. This is a case in which the infection traveled from the outside.

While curettage is indicated in cases of retained secundines post-abortionem, it is doing more harm than good when performed too late, say in a week or so, when the local infection has been already permitted to travel through the lymphatics and produce a general systemic infection. Curettage in such a late case may be instrumental in developing a pelvic cellulitis or pelvic abscess, or cause a septic peritonitis. At this late stage intrauterine douches combined with tonics are indicated.

Case III.—Mrs. R., 29 years old, married four years. Menstruation regular every four weeks for five or six days. No children, has had four miscarriages. No gonorrhœal history. Temperature and pulse normal. Examination presents normal-sized uterus, movable. Slight oöphoritis on both sides. As she applied for the relief of sterility, curettage had been advised and performed under strict aseptic precautions. For one week the temperature ranged between 98° and 99°, and the pulse was 90° when, on the eighth day while sitting in bed and lifting a child, she felt a sudden pain in the abdomen, associated with chills and fever, just as though something had burst. The temperature was now 102° to 103°. The chills continued, the abdomen was distended, and tympanitic and peritonitis set in. An examination showed a large mass in the posterior cul de sac, spreading into the two fornices. Incision gave exit to a large amount of ill-smelling pus. The patient succumbed to septic peritonitis two weeks after the curettage. The husband later admitted having had gonorrhœa before marriage. This was probably a case of dormant pyosalpinx aggravated by curettage, and ruptured later on into the abdominal cavity.

Case IV.*—Mrs. A. F., 21 years old; first menstruation occurred when she was thirteen years old, and was regular every four weeks, lasting four days. Has been married two and a half years. Had a gonorrhœa and gonorrhœal endometritis two years ago. About a year and a half ago she presented herself to her physician with a Hunterian chancre, followed later on by a macular eruption, for which she has been treated accordingly. Nine months later the physician was again called to attend her for abortion of a macerated six-months fœtus; the placenta was also degenerated and much adherent. Digital detachment was practised, followed by curettage. The patient was soon able to leave the bed, but two weeks later she had pain in the abdomen, uterine bleeding, temperature 101°, pulse 120. Examination revealed the presence of stringy bands of placental tissue in the uterus. A secondary curettage was ordered. While curetting the physician found the curette slipping behind the uterus, and partial collapse of patient indicated perforation. Laparotomy was performed and the uterine rent was closed. The right ovary and tube being degenerated, were removed. The patient made an uneventful recovery. Microscopic examination of the placenta showed an increased number of villi and a considerable proliferation of cells in the stroma about the vessels of the villi, almost entirely obliterating the lumen of these vessels.

This case clearly indicates the importance of clinical and microscopical observations in a given case prior to curettage, and also the ease and danger of perforation of a preexisting degenerated uterus.

A few remarks about the technique of curettage. The uterine sound should always be used to ascertain the direction of the uterine canal. Many a sharp retroflexed or anteflexed uterus has been perforated by the curette. One should avoid making too much traction upon the uterus with volsellum forceps; it may produce new traumatism in addition to the preexisting adnexal inflammations. Too forcible curettage may cause atresia of the uterine canal; packing of the uterus favors obstruction to free drainage, and is, therefore, abandoned by many gynecologists.

Intrauterine irrigations are not absolutely necessary. Swabbing of the canal with gauze removes the débris. Curettage and divulsion are unnecessary in cases of sterile women suffering from dysmenorrhœa due to anteflexion of the uterus. Dudley's operation for anteflexion gives better results as regards both dysmenorrhœa and sterility.

The uterus should be dilated to the full extent (according to Polk a half-hour should be consumed

*The history of this case has been kindly related to me by Dr. S. Rottenberg.

in this dilatation), and the finger introduced into the uterus, in case of retained secundines, in order to feel what we are doing.

A case has been reported to me, not as an anecdote, in which the whole placenta was expelled two days after a thorough curettage; a predigital examination would have prevented such a mishap. One should never curette the placental site even in cases of sapræmia.

From the facts above stated we see that it behooves us to look upon the traditional "womb cleaning" as a capital operation, and always to remember the saying, *"Multum ex parvo."* It behooves us, as caretakers of the public health, to be more painstaking, more investigating in cases of uterine symptoms, which are frequently only manifestations of obscure pathological lesions, every case being a law unto itself.

It is a dreadful experience for a young, ambitious practitioner to encounter a case of unsuspected, degenerated, malignant uterus and perforate the same, in the midst of tenement house surroundings. Hemorrhage is sudden and removal of patient to the hospital is not always possible. It is too late then to reproach the physician, who, in his sincere desire to help the suffering woman, was prepared only for a "cleaning of the womb," and found himself at bay, having no resources or knowledge of how to open the abdomen, ligate the rent, and save the woman's life. Such perforation of the uterus in a well-equipped hospital is easily overcome; such grave occurrence in a tenement house means danger to life.

I agree perfectly with a noted obstetrician, who said that the teachings of our colleges to regard minor operations as minor procedures are dangerous for the recent graduate. I plead for a more careful, discreet, and scientific application of curettage. If I have succeeded to-night in deterring some medical friend from the wholesale use of this simple but often dangerous operation, and if by so doing I have expressed the opinion of the more careful and conservative older practitioner, I shall be well repaid for having presented before you this paper, on a subject so simple as uterine curettage.

Copper in Canned Foods.—A wholesale grocer recently convicted in the Bow Street Police Court, London, of selling canned peas and beans containing four grains of copper sulphate to the pound was fined only £3 and costs, although he admitted that he had known of the presence of the adulterant.

Railway Travel in Germany.—Recent investigations by German health officers have shown that one runs more risk in traveling second-class on the railways of the Empire than in the third-class, because the wooden benches are not so likely to harbor bacteria as the cushions of the second.

GLUTTONY OR "FOOD POISONING" AS A CAUSE OF SYMPTOMATIC EPILEPTIC CONVULSIONS.

By WILLIAM P. SPRATLING, M.D.,
SONYEA, N. Y.

MEDICAL SUPERINTENDENT OF THE CRAIG COLONY FOR EPILEPTICS; PRESIDENT OF THE NATIONAL ASSOCIATION FOR THE STUDY OF EPILEPSY AND THE CARE AND TREATMENT OF EPILEPTICS; MEMBER NEW YORK ACADEMY OF MEDICINE, ETC.

The first few cases of symptomatic epileptic convulsions that I saw in middle aged men in which convulsive attacks invariably followed gross over-indulgence in eating and in drinking, did not impress me as constituting a class of sufficient importance to warrant their being placed in a group alone. But having seen 18 or 20 such cases during the past two years, I have come to believe that they represent a distinct phase of the subject that it is well worth calling especial attention to, particularly since they are usually so amenable to treatment; substantially all of them making satisfactory recoveries when treatment is promptly instituted and observed as long as the nature of the case requires.

The cases of this kind that do not turn out well under treatment are those in which the patient is unwilling to deny himself the pleasures of the palate, except spasmodically and immediately after he has had a convulsion. But unfortunately the lesson learned at such times is soon forgotten, and all such individuals stand in danger of ultimately becoming confirmed epileptics of the so-called "habit" type, and to suffer all the mental and physical accompaniments of that affliction.

Usually those who suffer in the way I am about to describe are between 35 and 45 years of age. Most of them are men of robust, frequently plethoric physique; all are hearty eaters; all lead more or less inactive, indoor lives, and some are heavy drinkers. When the latter factor complicates the case, the prognosis is less hopeful than when there is excessive food consumption only; not because the type of convulsions induced by alcoholic indulgence yields less easily to treatment, but because the drink habit is not so readily broken.

While it is true as a general rule that heredity plays but little part in the causation of epilepsy, when it originates anew after the twentieth year, I have found that it is quite frequently a factor of some degree in the cases in question. It seems that there need not be insanity, or alcoholism, or epilepsy, or some other nervous affection in the ancestors in such cases as these, but a stomach disorder of pronounced type, like an aggravated dyspepsia, may make its influence felt in some obscure way in the offspring.

A very intelligent professional man, 40 years of age, came under my care eight years ago. He was subject to symptomatic *grand mal* attacks that invariably appeared the day following gross dietetic indiscretions, such indiscretions usually occurring between midnight and 2 A. M. He had a weak stomach and could digest certain foods only. On investigation I found that his father suffered the better part of life in the same way. The father respected his nutritional peculiarity, but the son did not; so the father escaped anything more serious than a severe, periodic dyspepsia; while the son was threatened with becoming a confirmed epileptic. After having an attack while speaking in a public hall once, he realized his danger, changed his manner of living, and had been free from attacks for five years when I saw him last on November 24, 1904.

The primary cause of convulsive attacks in cases

of over-eating and over-drinking in certain individuals seems to lie, first, in a weak stomach, and, second, in some obscure disorder of metabolism. Not only is the amount of food habitually taken by such persons beyond all reasonable requirements, but it is usually of an improper kind, and is taken to gratify what seems to be an abnormal appetite.

The type of convulsion usually induced is of the *grand mal* variety, though it is not definitely fixed. So long as the attacks remain *grand mal* only, the case is less likely to pass into "habit" epilepsy than when the type changes. The last case of the kind I saw was that of a newspaper man, 38 years of age, who suffered grand mal attacks for some years, but whose dietetic habits were so atrocious that the seizures at the end of that time changed to infrequent *grand* and very frequent *petit mal*, with the result that some mental enfeeblement is becoming apparent, his memory in particular failing. This annoys him painfully, for in his work a good memory is a necessity. Along with the change in the type of his convulsions have come periods of marked automatism.

The day before I saw him he had a breakfast of cereals, eggs, fried potatoes, pancakes, and coffee; a hearty dinner at noon of a rich soup, chicken pie, several vegetables and pudding, with wine sauce for dessert; for supper he had a heavy meat pie, of which he ate heartily, three large baked potatoes, three pieces of apple pie, and three cups of tea; and yet he wondered why he suffered so much from headaches, from his stomach, from eructations of gas and flatulence, and attacks of momentary unconsciousness that were increasing in frequency, and that, worst of all, were fast undermining his mental faculties. He had written me two letters within a week, one on the day before I saw him, and yet he could not recall my name when I met him.

While the indications for treatment in such cases are plain enough, they are not so easily carried out. The cause of the convulsions must be sought in toxic states due to faulty metabolism. We must first eliminate waste and toxic products, and then plan a course of treatment which will prevent a recurrence of such products.

The first thing is to put the patient upon a low diet, and be sure to make it low enough. There are plenty of food stuffs that are light, nutritious, and easily digested that can be substituted for the grosser food stuffs such persons are accustomed to consume in large quantities. Then insist upon absolute regularity in taking food, and forbid its consumption under any condition after the early hours of the evening. Let the patient go to bed on an empty stomach. Cut off all meat for supper and breakfast, and teach the patient to have a wholesome respect for cooked fruits, bread and butter, toast, milk, chocolate and cocoa, eggs, and other such things for supper. If there is a tendency to constipation, correct it by daily doses of the fluid extract of cascara sagrada, given some time before breakfast. Stop all use of alcohol, and if the patient is irritable, nervous, and his attacks show a tendency to recur under the low dietetic regime, put him on a nerve sedative made up so that each dose represents 10 to 15 grains of an equivalent of bromide of potassium. This drug will not cure the trouble, but it will be useful in allaying cortical irritability while reconstructive and eliminative therapeutic measures are being applied.

Let the patient take as much outdoor life as possible, the more the better. Hydrotherapy is of great value.

Under this simple regimen and course of treatment the majority of such cases soon experience great relief and eventually complete cure. But let such patients understand that they can keep well only by right living.

MARKED MENTAL IMPROVEMENT FOLLOWING OPERATION FOR DEPRESSED FRACTURE OF SKULL.*

By B. VAN D. HEDGES, M.D.,
PLAINFIELD, N. J.
SURGEON TO MUHLENBERG HOSPITAL.

MARKED mental and moral improvement in a lad of eight years, following operation for depressed fracture of the skull, is the history in brief of the patient I have the privilege of presenting before the Section this evening.

I first saw the boy in October, 1903. He was brought to the Clinic of Muhlenberg Hospital in Plainfield, by his mother, who was anxious to know if his condition could be relieved by any operative interference. He was the youngest of seven children, the others all living and of sound mind and body. No specific, tuberculous, rheumatic, or neurotic family history. Until the age of four, his development in every way seemed perfectly normal. He was then accidentally hit on the head by a brick, and as a result was confined to the house for some weeks. When he recovered his mother noticed a marked depression in the bone at the seat of the injury. From this time on, that is, for the next four years, there was evidence of a decided change in his mental and moral make-up. Intellectually he seemed to reach a standstill. His mind appeared incapable of grasping even the simplest rudiments of instruction, and if an impression was made at any time he seemed to forget it all the next day. It was with difficulty, also, that he could give expression to his wants; such simple words as "milk" and "water" often failing him entirely when needed.

But even more pronounced than his backward mental condition was a curious moral obliquity. For example, he seemed to have no regard whatever for the rights and ownership of property. If he saw a bicycle that suited his fancy, in his neighbor's yard, he would immediately appropriate the same to his use and proceed to ride it home. Severe punishment for such an act would not deter him in the slightest from repeating it the next day. His disposition, which prior to the accident seemed perfectly normal, took such a vicious turn that none of the neighbors would allow their children to play with him. At the slightest provocation, sometimes without any provocation whatever, he would show violent outbreaks of temper and attempt personal violence upon any who might be near at hand. His language, such as he could command, was at these times most indecent. He lied on all occasions and seemed to elect falsehood by preference; the truth was not in him. Moreover he seemed utterly devoid of all natural love for his family. Such was the condition of the boy for which his mother sought relief.

Physical examination of the little fellow showed him to be perfectly well in every way save for the depression in his skull. This was found to be about one inch in diameter, one quarter inch in depth, situated in the median line along the course of the sagittal suture, the center of the depression being one inch and a half anterior to the vertical point, and four and one-half inches from the glabellar point.

The boy was admitted to the hospital and kept under observation for a week, at the end of which

* Read before the Pediatric Section, N. Y. Academy of Medicine, December 8, 1904.

time I operated, assisted by my brother, Dr. E. W. Hedges. A horseshoe incision was made with the base anterior so as to insure a good blood supply for the flap. After dissecting back the periosteum, the entire area of depressed bone was removed. The underlying dura was slightly adherent to the bone in places, but was easily detached without injuring the longitudinal sinus. The dura was not opened. It looked thick but in other respects seemed normal. The periosteum and skin were then brought together with catgut and silk worm respectively, and the subsequent convalescence was perfectly normal in every way—the patient leaving the hospital at the end of three weeks.

Over a year has now elapsed since the operation, and we are in a position to note what changes, if any, have occurred. During this time I have seen the boy at frequent intervals myself and have had him carefully watched by his mother and those with whom he has been thrown in contact. The improvement has been most satisfactory. He now not only seems to grasp the meaning of what is said to him, but can also express himself with a considerable degree of intelligence. He knows his letters and seems to show more than ordinary aptitude in his lessons.

Moreover he has a realizing sense of his moral obligations to those about him, and plays with other children of his age without any of the former violent outbreaks of temper. He tells the truth, his language is decent, and he does what he is told. He also seems to have developed a proper love and affection for his mother, sisters, and brothers.

One of the most interesting features of this case is the further light it seems to throw upon work that has already been done in determining the functions of the prefrontal area, anterior to the motor zone—the point at which the depression occurred.

Church and Peterson state that "while it is true that this region may be largely destroyed by injury or disease without producing localizing symptoms, there is a rapidly growing number of cases indicating that mental and moral obliquities are usually the sequence of such lesions. Ablation of the prefrontal region in dogs and monkeys induces a change of character, of disposition, of behavior, that is clearly recognizable.

"In men with prefrontal brain injury, mental sluggishness, want of attention, diminished memory, and loss of energy and self-control, are noted with more than coincidental frequency."

Adolph Meyer in an article on "Brain Traumatism," in the *American Journal of Insanity* for Jan., 1904, reports several cases similar to the one here recorded, in which operation gave complete relief.

The conditions present before operation in this case were so distressing, the cause of the trouble so apparent, and the results following operative procedure so eminently satisfactory, that I have felt warranted in giving this brief history and also in presenting the boy for inspection.

Plague Rats Put to Use.—Some time ago the Japanese offered a bounty of two and a half cents for each rat captured and killed, in order to check the dissemination of the bubonic plague. Over a million pelts were brought in, and these, after disinfection, were made into ear muffs for the army.

Longevity in Warm Climates.—Statistics seem to show that living in subtropical climates is conducive to length of days. According to the *Mexican Herald*, men and women beyond the one hundred year line are common in that country, and Spain, with its relatively small population, is said to number 401 centenarians among its inhabitants.

GEHEIMRATH DR. DETTWEILER.

EULOGY PRONOUNCED ON THE OCCASION OF THE FIRST ANNIVERSARY OF HIS DEATH.*

By S. A. KNOPF, M.D.,
NEW YORK.

A YEAR ago, on January 13, 1904, Privy-Counselor Dr. Peter Dettweiler died at his villa at Cronberg, near Frankfort-on-the-Main. His death was such as he had always desired it might be, without previous invalidism. He died of an apoplectic stroke, while sitting at his desk, writing.

In presenting his photograph to the Academy, I desire to recall in a few words the life and works of this great man. Dettweiler was born at Wintersheim in Hesse, August 4, 1837. He studied at Giessen, Würtzburg, and Berlin, and took his medical degree in 1863. During the Danish-Prussian (1864), Austro-Prussian (1866), and Franco-German wars (1870-71) he served as an army surgeon. In the performance of his duty he contracted tuberculosis, and resigning from the army went as a patient to Brehmer's sanatorium in Goerbersdorf. Regaining his health, he became an enthusiastic

assistant to Dr. Brehmer. In 1873 Dr. Dettweiler published his first work "Die rationelle Therapie der Lungenschwindsucht in Goerbersdorf," which attracted considerable attention. After six years' service at Goerbersdorf Dettweiler became the founder of the celebrated sanatorium at Falkenstein, which, up to this date, is the Mecca for students of modern phthisiotherapy from all over the world. From everywhere, where sanatorium treatment has taken a foothold, physicians come to Falkenstein to see the institution and learn its methods, and many of our foremost American specialists in tuberculosis have paid a visit to this institution and its distinguished director.

It should be said of Falkenstein that the place was selected without special regard to climate—a rather

*Read in connection with the presentation of Dettweiler's picture to the Academy of Medicine, at its regular meeting, January 19, 1905.

new idea at that time. It is only an hour's ride from Frankfort-on-the-Main, and only 1,300 feet above sea level. At the time Dettweiler founded this sanatorium, Brehmer's teachings that much higher altitudes were necessary for the treatment of pulmonary tuberculosis were considered authoritative.

Dettweiler was one of the first to consider the climatic condition in the treatment of tuberculosis, as of secondary importance. Among his other greatest achievements must be counted the inauguration of the rest cure on the reclining chair in the open air, and the foundation of the first sanatorium for the consumptive poor, now located at Ruppertshain. Germany is in a large measure indebted to him for its now numerous sanatoria for the people. It was my privilege to serve under Dettweiler as assistant when, still in the prime of life, he was medical director of Falkenstein, and I had frequently occasion to observe his many acts of charity as physician, neighbor and friend. Dettweiler was a man of unusual cordiality and kindness, yet of a strong personality. He could be stern and severe when occasion demanded. His power over the inmates of the sanatorium was wonderful. He studied the soul life of every patient; he was his friend, confessor, and physician. The sanatorium patients were greatly attached to him, and the anniversary of his birth was a holiday at Falkenstein. From all over the world came messages of congratulation from former patients. It was the gratitude of his wealthy patients which enabled Dettweiler to establish the first sanatorium for the poor. To his assistants he was an ideal chief, always helpful, kind, and considerate. Visiting physicians and others interested in sanatorium work were sure of a hearty welcome; to Americans he was particularly cordial and he often expressed to me regret for his inability to converse in English.

Dettweiler's book "Die Behandlung der Lungenschwindsucht in geschlossenen Heilanstalten" (the treatment of phthisis pulmonalis in closed establishments), which has appeared in three editions, has become classic and is still the authoritative work in all matters appertaining to the sanatorium treatment of consumptives. He was the inventor of a most ingenious device for the prevention of the spread of tuberculosis through indiscriminate expectoration. It is an elegant little pocket cuspidor of blue glass which can be manipulated with one hand and hidden in the folds of a handkerchief.

Like our own beloved Trudeau, Dettweiler became a great physician and benefactor of mankind as a result of having been himself afflicted with tuberculosis. In seeking to cure himself, he sought at the same time to cure others and gave to the world the results of his own experiences and sufferings. He was a great lover of art, a skilled amateur sculptor and painter, and a deep student of philosophical and metaphysical works. He was a hygienist in the highest sense of the word and an ardent advocate of cremation. In compliance with his last wish, his body was cremated three days after his demise.

Dettweiler was the ideal sanatorium physician for consumptive sufferers. I believe I cannot do better in closing this feeble tribute to a beloved master to whom I owe so much and who has been a guide and inspiration to me ever since I entered upon my work in phthisiotherapy, than quote from the memorable address which he delivered in 1899 at the occasion of the first Congress on Tuberculosis, his conception of what a sanatorium physician should be. "The medical director of a sanatorium for consumptives should not take upon himself the responsibility of such a position unless he is fully prepared and honestly feels that he can excel his coworkers in strength, creative power, discretion, faithfulness, and duty. Otherwise, he is no better than a hired employee, too weak for the great and uplifting cause of service to his fellow men, which at the end of this nineteenth century has grown to such great heights, and which promises so much for suffering mankind."

At this time when, in the combat of man against man, heroes are being worshipped according to the number they slay in battle, it is inspiring and elevating to be permitted to pay tribute to a man who won glory in fighting disease and through whose personal devotion and skill thousands of useful lives have been saved and made happy.

Symptoms of Bone and Joint Diseases in Children.—Stewart L. McCurdy believes that half of the mistakes that are made in diagnosis are dependent upon lack of thoroughness in making the examinations of the patient. Young practitioners are too apt to look for rare conditions, while older physicians, having become too accustomed to the commonplace, do not recognize the unusual conditions until it is too late to avert disaster. In many of the more chronic diseases of children the symptoms develop insidiously. For this reason the physician often does not see the child till the disease is well advanced. An apparent change in attitude, a limp, or a weariness, should not be considered a "habit." "Growing pains" more or less persistent should not be overlooked. The early pain of tuberculous spinal disease of the lower dorsal region is often in the abdomen. Difficulty in breathing without corresponding symptoms of pulmonary diseases should suggest upper dorsal disease. Continuous pains in the region of the pelvis, hips, and thighs must always suggest lumbar and sacral disease. Curvature of the spine, when the curve is not an acute angle, but the segment of a circle, is usually due to scorbutus or rickets, and not to Pott's disease. Many patients are brought to the physician for jackets when such treatment is not required. The pain and emaciation of scorbutus must not be confounded with these symptoms as occurring in tuberculous diseases. Again, early Pott's is often treated for indigestion, peritonitis, intestinal catarrh, or liver disease. In chronic tuberculous diseases, the only marked symptom is an obscure limp or rigidity of a joint. Fever occurs between three and five o'clock in the afternoon only. The most common error is in calling everything with an acute pain, that cannot be attributed to a definite cause, rheumatism. The writer declares that no local pain in bone or joint or any part of the body, should be called rheumatism. Acute periostitis of bones of the extremities is often diagnosed as rheumatism. The writer believes that fifty per cent. of all so-called bone and joint diseases are in children with syphilitic ancestry, and that fifty per cent. of all synovial diseases of adults are either syphilitic or gonorrheal. Hysterical cases should be carefully sifted, and by good management these patients should be made useful members of society. In obscure cases consultation should be sought before it is too late. Deformity from Pott's disease is no longer necessary when the case is seen early. Scoliosis should never advance, but should be improved. The majority of tuberculous hip joints should recover without shortening or angular deformity. Tuberculous joints of the extremities should be treated early enough to prevent their advance to suppuration and destruction of functional usefulness.—*The Columbus Medical Journal*

New York State Charitable Institutions.—Without counting the new hospital for the care of incipient tuberculosis at Ray Brook, the fifteen charitable institutions of New York State comprise 353 buildings, which occupy 3,914 acres. These institutions have a total capacity of 9,153, and represent a total valuation in real and personal property of $9,491,508.36

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THOMAS L. STEDMAN, A. M., M. D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, January 28, 1905.

THE TREATMENT OF TYPHOID FEVER.

IN the treatment of no disease, unless perhaps it is pneumonia, is there such a variety as in that of typhoid fever—and yet at the same time in none is there greater monotony. Almost every physician who is called upon to see many cases of this disease, after trying various methods and testing one new or popular theory after another, gradually settles down into a more or less unvarying routine—not always to the advantage of his patients. But with most of us there is still an uneasy feeling that perhaps we are not doing the best we can for those who place their lives in our keeping, and for this reason perhaps there is nothing more interesting than to learn how others are doing and what success they are having.

Dr. F. Foord Caiger, who was the Bradshaw lecturer for 1904, took as his theme the treatment of typhoid fever, or enteric fever as it is usually called in England. The lecturer speaks with the authority conferred by a wide experience—he is medical superintendent of the Southwestern Fever Hospital, Stockwell—and the résumé he gives of his usual practice in the treatment of typhoid fever is therefore of more than ordinary weight and possesses the interest inseparable from a narrative of personal experience. In his introductory remarks, Dr Caiger referred to the fact that the case mortality of typhoid fever in England remains at a height of more than 15 per cent. The treatment of typhoid fever is necessarily conducted on one or two lines, viz., an active remedial method or a passive or so-called expectant method, each of which has its firm adherents. The three methods of treating enteric fever by means of remedies which are assumed to be capable of exerting a direct controlling influence over the natural course of the disease may be designated as the specific, the antipyretic, and the antiseptic, according to the nature of the agents employed.

The hope that the serum treatment of typhoid fever would prove as valuable as in the case of diphtheria has not been fulfilled. However, in this connection it should be mentioned that Chantemesse claims to have produced a serum, the nature of which is not known, the use of which in enteric fever is said to have met with remarkable success. Wright's method has also had some considerable degree of success.

An antipyretic effect may be produced either by drugs or by the direct application of cold to the body surface by baths, packs, sponging, etc., or by a combination of both. Quinine is undoubtedly the best drug for this purpose. It possesses a marked antiseptic influence over living cultures of the typhoid bacillus, and its administration is not attended with cardiac depression. For the purpose of lowering the temperature, quinine must be given in large doses—15 to 20 grains or more, twice in the 24 hours. Or a still better method is to give it in four 7½ gr. doses repeated at intervals of 15 minutes in the evening of every third day during the first fortnight of the fever. In cases of moderate fever, the writer does not favor the use of antipyretic drugs, at least in antipyretic doses. He believes such pyrexia to be a natural element of defence against bacterial invasion. In cases of excessive pyrexia, however, vigorous antipyretic measures are indicated. The cold bath is the most effective method of applying cold to the surface. Its contraindications are well known. It is probable that the cold bath owes its superiority over all other therapeutic measures of which the chief aim is refrigeration to its salutary influence on the nutrition of the skin and kidneys. The "graduated bath" has been widely recommended.

Although it is now recognized that any attempt to destroy the bacilli in the lower intestinal canal by the administration of antiseptic drugs by the mouth is futile, unless given in such doses or in such strength as greatly to injure the patient, still it is not unreasonable to expect that they might be capable of exerting some restricting influence on the multiplication of bacteria in the mucous membrane and contents of the bowel. This is positive in respect to the various putrefactive organisms, for there is a decided decrease in the fetor of the stools after the use of antiseptics. The writer calls attention to the good effects, in suitable cases, of calomel before there is much diarrhea. But in certain cases, even when it is given not later than the end of the first week, it causes intestinal irritation which is prejudicial to the patient. The writer has been so impressed with the fact that he has given up the routine use of calomel in the early stage of typhoid fever, and limits himself to its use in cases in which there exists some special indication for this drug. Perchloride of mercury has been highly recommended as an intestinal antiseptic. Although Dr. Caiger believes that some of the antiseptic remedies distinctly influence in a favorable manner the course of an attack of typhoid fever, still he does not believe that they are capable of cutting short the attack or of lessening to any appreciable degree the risk of hemorrhage, perforation, or relapse, as some have contended. He mentions some other antiseptic remedies, among which are sulphurous acid, oil of turpentine, the combination of quinine and nascent chlorine, and the essential oil of cinnamon. His results so far with the oil of cinnamon have been favorable. Among 147 cases, there was a mortality of 9.5 per cent. The temperature ran lower in these cases than the average in typhoid cases, the patients for the most part remained drowsy throughout their illness, thus enjoying mental rest, and delirium was less frequent. Intestinal decomposition was controlled in a striking manner, no single instance of meteorism occurring among the 147 cases in which this remedy was used. It is well, the author says, to begin with small doses, for example, 2½ minims, increasing this to 4 or 5 minims in the course of a few days. Laboratory experiments with this oil have been likewise encouraging. In cases in which there is any suspicion of circulatory failure, he gives a grain of sulphate of quinine with each dose.

Dr. Caiger believes that the adoption of an entirely expectant treatment is not only fallacious in its con-

ception, but very mischievous in practice. In the absence of a specific, he would treat a case of typhoid fever on symptomatic lines, and in addition would employ from the earliest possible date either antipyretic or antiseptic remedies, or both, as might appear especially suited to the attack and to the individual in question. In the treatment of toxemia it is always well as a preliminary measure to rid the lower bowel of its putrid and offensive contents. Calomel is most effective for this purpose. Soap and water enemata, with the addition of turpentine, are also useful, as is the oil of cinnamon. The cinnamon treatment is also especially serviceable in cases with nervous manifestations. It is most important for the victim of typhoid fever to obtain mental rest. For this purpose opium is valuable. In ataxic cases, a combination of quinine and chlorine is excellent. In the treatment of pyrexia, Dr. Caiger much prefers the cold pack to the cold bath. If the effect of this treatment proves temporary, the pack should be repeated and sulphate of quinine, 15 to 20 grains, combined with 15 to 20 minims of laudanum should be given. The administration of quinine usually prolongs the effect of mechanical refrigeration. In cases in which restlessness and insomnia do not yield to cold sponging, one of the numerous hypnotic drugs may be tried. If diarrhea and abdominal pain are present, the preparations of opium are especially useful. If the number of stools exceeds more than four or five in the course of 24 hours, the diarrhea should be controlled. If the feeding is not at fault, a starch and opium enema is indicated. Cold abdominal compresses are of value when definite tenderness exists. Constipation is well treated by a soap and water enema, not exceeding a pint in the morning of every third day. In cases of cardiac failure, strychnine, quinine, or digitalis may be given. There are special indications for the employment of alcohol, but the lecturer thought that in most cases of enteric fever, alcohol is not only not required but its employment is occasionally distinctly harmful. In cases of intestinal hemorrhage, he said, that after having seen that the patient receives a full dose of opium and that an icebag is carefully applied to the abdomen, the treatment may be summed up in the simple word "precaution." The complete deprivation of fluids, except an occasional fragment of ice is most important in these cases. As to the management of perforation, the lecturer was in complete accord with those who hold that a moribund condition of the patient should be the only contraindication to operation in such cases. And as to the most favorable time for operation, "there is no time like the present." A careful examination of the abdomen should be made daily in the course of typhoid fever, as then any change in its condition will be more accurately perceived.

Dr. Caiger was fortunate in his choice of a subject for the Bradshaw Lecture, and his hearers were fortunate in being able to listen to so good a dissertation on such an important subject as that of the treatment of typhoid fever.

Prison Accommodations Unsanitary.—In his report to the State Commission of Prisons made last week, State Inspector John P. Jaeckel makes serious objections to the condition of several New York city police station houses, and to the practice of confining there prisoners accused of crime without discrimination. He also recommends reforms at Clinton Prison, where a large majority of the State's consumptive convicts are confined.

THE PATHOGENESIS OF SYPHILITIC RECRUDESCENCES.

THE clinical course of syphilis presents so many puzzling features that it has always furnished a fruitful source of speculation to pathologists. The fact that a disease may give rise to repeated relapses years after its beginning and that serious sequelæ not infrequently develop after even decades of apparent health, is sufficiently curious to account for the circumstance that even the master minds of medical science have not been able to furnish unassailable explanations for the phenomenon. At the present day theorists are necessarily hampered by a lack of knowledge as to the contagium concerned, and it is probable that only the discovery of the exact character of the syphilitic virus and its relationship to the various pathological changes manifested by different phases of the malady will permit a satisfactory insight into the nature of the disease process. So long as this remains obscure, the problem must be approached from the clinical side, and the chances of error are necessarily large.

Virchow considered that the spasmodic character of the outbreaks indicated an irregular outpouring of active virus into the blood, thus giving rise to virtually fresh infections. The lymph nodes were to be regarded as the depositaries of the latent virus, which from time to time was set free, entered the blood, and brought about a renewal of the symptoms.

Finger adopted a radically different stand and assumed a bacterial nature of the virus as his point of departure. In an extensive critical study, published in 1890, he came to the conclusion that the primary and secondary lesions were caused by the virus itself, but that the immunity and tertiary symptoms were the result of metabolic products of the virus which gave rise to special reactions of the organism leading to the development of the late manifestations. This view was supported by the *quasi* chemical affinities of the two types of lesions, the early ones due to the virus responding to mercury, whereas the others, depending on the reaction products, are most easily influenced by iodine.

Lesser, in a contribution to the recent *Festschrift*, dedicated to Senator, adopts the older hypothesis of Lang. This author presupposes that at the time of infection the virus is carried by the blood into all the tissues, and occasions the early manifestations. The virulence of the deposited contagium gradually abates, but it still for a time retains the ability to incite recrudescences of the symptoms. After a variable period it is either partially or entirely destroyed, and in the former cases is modified to such a degree that it loses its infectious nature. During this period of dormancy it remains quiescent unless some, often external, stimulus provokes it into action and gives rise to the late manifestations of the disease. This view is in harmony with the clinical observation that the early lesions are apt to be symmetrical while the late symptoms are characterized by asymmetry. Lesser cites several cases in support of this theory, in which recurrences of the skin eruption took place in the pigmented spots left behind by the first exanthem. He summarizes his conception of the matter by stating that in the eruptive stage the entire body is flooded with syphilitic poison, and that this is deposited more or less uniformly in numerous foci which serve as sources of relapse during the course of the disease. As the length of time after infection

increases, more and more of these persisting germs perish and they may finally disappear completely.

The practical bearing of this assumption lies in its application to the therapeutical management of the disease. In order to hasten the diminution and neutralization of these depots of latent virus frequent repetitions of the course of medication are necessary, and the advocates of intermittent mercurial treatment should find a potent argument for their cause in this theory of the pathogenesis of late syphilitic manifestations.

The Evil Effects of Alcohol and Smoking on Young Soldiers.

Major P. G. Tevers, R. A. M. C., writing in the *Journal of the Royal Army Medical Corps* on the above subject, expresses the opinion that alcohol is seldom, if ever, needed by the soldier, and declares that the habitual use of alcohol in any form is not necessary to the animal economy. With regard to smoking, Major Tevers states that in England the practice of cigarette smoking is becoming so common amongst recruits of a certain class—especially those raised in towns—that it is rare to find them without fingers stained from the smoke, which only too often tells its own tale. On referring to the recruiting returns of the Manchester district, for example, for the year 1901, we find that out of 11,896 who presented themselves only 3,076 were accepted, and the recruiting officers declare that one of the chief causes of this rejection is the widespread habit of cigarette-smoking. The experience of American army recruiting officers at the time of the Spanish-American war, with regard to cigarette smokers, is said to have been similar to that of the English. Upwards of 90 per cent. of cigarette smokers who offered themselves as soldiers were rejected.

Major Tevers endeavors to show that the mental effects of cigarette smoking are as injurious as the physical, and earnestly warns young soldiers not to acquire the habit, as once established, it will continue to old age.

There can be no doubt that cigarette smoking by youths is greatly on the increase both in the United States and in Great Britain, and when it is carried to excess, especially when the smoke is habitually inhaled, there can also be no doubt of its baneful effect. This is a statement the truth of which is universally conceded, even by cigarette "fiends" themselves, who call the paper cylinders "coffin-nails." There is thus no need for further discussion of the fact; what is needed is a practical remedy for the acknowledged evil. The usual or only remedy proposed, and which has been actually tried by some State legislatures, is prohibition. This may reduce slightly the number of cigarette smokers, but what little it may accomplish can only be at a tremendous sacrifice of personal liberty, and it will in the end as surely fail as the attempt to repress beer drinking on Sunday in this city has failed.

Report of the Tuberculosis Commission of the State of Vermont.

The Tuberculosis Commission of the State of Vermont, appointed in 1902, has issued recently its first report. In 1903 there were 441 deaths from tuberculosis in Vermont, an annual death rate of 12.8 per 10,000 of population, and it is believed that there are at the present time at least two thousand consumptives in the State. Considering that Vermont is a strictly rural state, possessing hills, mountains, pure air and water, the prevalence of consumption denotes that there must be factors predisposing to the disease. According to the report the prime factor is undoubtedly a climate so rigorous that the people of Vermont spend a large part of their lives indoors, in living and sleeping rooms not only poorly ventilated, but almost hermetically sealed and heated to an unnatural degree.

The following are the conclusions reached by the commission: (1) Consumption is a communicable disease, responsible for one-tenth of all deaths. (2) It is not hereditary, as we understand the term, but inherited tendencies may increase the liability of contracting the disease. (3) Treated properly in its early stages, consumption can be arrested in the majority of instances, and through simple precautions in destroying infective material its spread can be almost entirely controlled. From this the natural expectation follows that consumption can ultimately be conquered and relegated to an unimportant place as a cause of death. (4) Study and experience has demonstrated beyond controversy that the only successful treatment of tuberculosis to-day is that known as the open-air treatment, which can nowhere be administered with results equal to those obtained in modern sanatoria. (5) If the above premises are correct, then the State owes it to her citizens, not only for economic and humanitarian reasons, but in the interests of the well and the preservation of the public health, to establish a sanatorium for the care of incipient cases of tuberculosis, especially those in indigent circumstances. (6) In the event of any reason arising making advisable the postponement of the establishment of a State sanatorium, then it is earnestly recommended that a special tuberculosis commission be provided for by an appropriation sufficient to properly carry on the conflict with tuberculosis, a conflict which means so much to the health, wealth, and happiness of not only an afflicted class, but the people at large—directed as it will certainly be toward the relief of suffering, the restoration to usefulness of a large class, and, above all, the protection of the well.

Beriberi.

The late Dr. Louis Vintras contributed to *The Hospital*, November 26, a paper on beriberi which possesses particular value at this time in view of the reported ravages of the malady in the Japanese army which is in other respects so well guarded from the attacks of disease. Dr. Vintras had had a long experience in observing the disease while in Brazil and the Guianas, and his conclusions are therefore of interest. His belief was that the malady is neither endemic nor epidemic, but is primarily due to privations and faulty nutrition, and that both white and colored people are equally liable to it. He states, moreover, that as Professor Achermann, the President of the Norwegian Commission on the disease, has recently established, there is no essential difference between Asiatic beriberi and ship beriberi. The difference in the symptoms on which it has been sought to lay so much stress, is a difference due simply to the conditions under which the patients find themselves, and not to any fundamental pathological difference. For the symptoms differ as largely among Asiatics as they do among the members of white crews, nor can it be said that the form it assumes is more severe with the one class of patients than with the other.

The writer pointed out an important pathological feature in connection with the disease, which is that when the damage done to the nerve endings has reached a certain point, though the progress of the disease may be arrested, the affected parts of the

nerves do not recover and the paralysis and subsequent deformities are irremediable.

Dr. Vintras summed up as follows: "Beriberi will appear wherever life is dependent for any length of time on foods, whether animal or vegetable, whose nutritive value has become impaired, more especially when people are at the same time subjected to heavy physical strain or to long exposure in debilitating climates. Our present knowledge of dietetics is too imperfect for us to formulate the exact relations between the different constituents of our foods and the different tissues of the body. Otherwise, knowing that it is the nerves which are primarily affected in beriberi, we should be able to say what is the particular impairment in food generally which is responsible for the causation of this disease."

News of the Week.

The Illinois State Association for the Prevention of Tuberculosis was recently organized in Chicago. The Association will endeavor to obtain from the Legislature an appropriation of $250,000 with which to build a State sanatorium, and the enactment of a law compelling the registration of all tuberculosis sufferers in the State. Any city or county interested in the combating of tuberculosis may be affiliated with the Association upon application to the Central Council. The dues are $1 annually. The Secretary is Dr. Arnold C. Klebs.

Dr. Chas. A. L. Reed of Cincinnati has been appointed by President Roosevelt as one of the two members from the United States to the joint commission which is to settle the dispute between the United States and the Republic of Panama over certain property rights. Mr. T. T. Gaff of Washington is the second. Their duties will be to appraise private property in the canal zone which is to be used in the construction of the canal. Two commissioners will be appointed by Panama, and the British consul will also act. The commission is to meet in Panama February 7.

Long Association of Doctor and Patients. — Dr. James H. Payne of Boston, who was graduated from the University of the City of New York in 1848, has three patients on his visiting list to-day who have been his patients upwards of fifty years; and he has another patient in good health from whom he removed an ovarian tumor 32 years ago. This patient is now 91 years of age.

Fatal Influenza in Chicago.—According to the weekly bulletin of the Chicago Health Department, influenza is more prevalent and more fatal in that city this winter than at any time since the epidemic there of 1891. In that year influenza was the chief agent in increasing the death-rate more than one-fifth over that of 1890, and numbers of the survivors have never since regained their former condition of mental and physical health.

Insanity Increasing in Connecticut.—The annual report of the Superintendent of the Connecticut Hospital for the Insane shows there were 2,259 patients in the institution for the year ending September 30, 1904. The superintendent says that insanity is increasing largely in the State, but the statistics show that this increase is especially among the foreign-born rather than natives. Although the native insane have increased to some extent, they have not done so in any such proportion as is apparent among the foreign elements. "In 1900 the foreign-born population of the State comprised 26 per cent. of the entire number. From 1898 to 1902, four years, 38 per cent. of the admissions to the hospital were of foreign birth and parentage. In other words, the 26 per cent. of foreign population furnished 38 per cent. of insane during those four years."

The Smoke Nuisance in Washington. — A Congressional resolution has been passed directing the District of Columbia Committee of the House to cause an expert investigation of the smoke nuisance to be made, with a view to abating it. The resolution recites that the report of the committee should embrace an enumeration of the most serious offenders and be accompanied by recommendations as to appropriate remedies and necessary legislation, supervision, and control. Which reminds us that there are some very flagrant offenders against the New York smoke ordinance among the large hotels in this city.

A Scared Commissioner in Chicago. — The peripatetic sanitary commissioner of *The Lancet*, who has been inspecting this country for some time and from petulance has advanced to a state of chronic disgruntlement apparently believed he had struck the limit when he landed in Chicago preliminary to an investigation of the slaughtering methods of the beef trust. "At Chicago," he says, "the sky was black, though there was no fog or mist, and huge clouds of dense smoke spread over the city like a pall. The streets were dark and gloomy, and being hedged in on either side by ugly houses ranging from ten to twenty storeys in height it seemed, on leaving the station, like penetrating some sinister ravine rather than walking along the best streets of a great and wealthy city. But for the gas burning in the shop windows and various electric advertising contrivances it would have been quite difficult to see. At rare intervals a little pink speck indicated that some abortive effort had been made at electric lighting and that was all the trace noticeable of municipal enterprise. Miserably slow horse tramcars rumbled along badly paved dark streets where desperate men not infrequently stop and rob pedestrians." One would think the poor man had never been in London.

Model Tenements in New York. — Mr. Henry Phipps, it is announced, has planned to give one million dollars for the erection of improved tenement houses in this city. An organization will be formed to carry on the work, and it is proposed to apply the net income from the rents to the erection of additional houses.

Yellow Fever on the Isthmus. — Reports from Washington state that yellow fever is gaining hold in Panama in spite of hard efforts to check it. A recent public health report shows seven cases in December and three new ones from January 1 to 10. The isthmian canal commission has cabled to Gov. Davis of the canal zone calling attention to reports of the prevalence of yellow fever on the isthmus, and asking for a report on the conditions. The commission is shipping a large amount of medicinal supplies to the canal zone to aid in the sanitation of that region. Immense quantities of rolled sulphur and insect powder have been sent there, an average of 2,000 pounds of the latter being shipped weekly.

Sickness in Zion City.—It is reported in Chicago that Dowie, the great "healer" of Zion City, has chronic gastric catarrh; his wife has long suffered from severe nervous prostration; the chief of police of Zion has empyema, and several other inhabitants of the place are seriously ill. The supply of spiritual medicine appears to have run low, or it may be a case of substitution.

Lecture at the New York Skin and Cancer Hospital.—Dr. Bulkley's usual clinical lecture at the

New York Skin and Cancer Hospital will be replaced on Wednesday, February 1, by a lecture by Dr. Boleslaw Lapowski on the "Treatment of Syphilis," and on Wednesday, February 8, by a lecture by Dr. Charles Mallory Williams on the "Treatment of Acne."

Dr. S. Weir Mitchell has been re-elected President of the Franklin Inn Club, an organization of literary men of Philadelphia.

Pathological Society of Philadelphia.—The Annual Exhibition Meeting was held on January 11 and 12 in the Mütter Museum of the College of Physicians of Philadelphia, an elaborate exhibit of a great variety of classified specimens being made. On the evening of January 11 demonstrations were made as follows: Dr. Joseph McFarland, "How Metastases Occur in Malignant Tumors"; Dr. M. H. Cryer, "The Variations in the Frontal Sinuses"; Dr. W. T. Longcope, "A Series of Aneurysms"; Dr. W. E. Roberston, "A Series of Hearts and Aneurysms"; Dr. Randle C. Rosenberger, "Cardiac Pathology"; Dr. Brooke M. Anspach, "Gynecological Pathology." On the evening of January 12 the following demonstrations were made: Dr. A. J. Smith, "Structure of the Distoma Pulmonale"; Dr. Y. White, "Tuberculosis in Man and Lower Ani-Funke, "Diseases of the Alimentary Canal"; Dr. C. mals"; Dr. C. H. Frazier, "Tumors of the Thyroid and Salivary Glands"; Dr. A. F. Coca, "Peculiar Bodies in the Serum of Artificial Blisters on a Syphilis Eruption"; Dr. D. J. McCarthy, "Cerebral Arteriosclerosis."

The Bourbon County, Ky., Medical Society met at the offices of Dr. W. C. Usseng, Paris, Ky., on January 19. The following papers were read: "Diagnosis of Appendicitis," Dr. Wm. Kenney; "Treatment of Appendicitis (Surgical)," Dr. Robt. Crothers, Cincinnati; "Is there a Medical Treatment of Appendicitis?" Dr. Joseph Eichberg, Cincinnati; "Relapsing Appendicitis," Dr. A. H. Keller, Ruddles Mills, Ky. The discussion was opened by Dr. J. S. Wallingford.

The Cincinnati Society for Medical Research held its regular monthly meeting at the Cincinnati Hospital January 19. The program was as follows: "Experimental Decapselation of the Kidneys" (with lantern slides), Dr. H. J. Whitacre; "Myoma of the Skin" (lantern slides), Drs. Heidingsfeld and Markley; "An Attempt to Relieve Atrophic Rhinitis by a New Operation" (presentation of patient), Dr. S. Iglauer.

Philadelphia County Medical Society.—At a stated meeting held January 18 the following officers were elected for the ensuing year: *President,* Dr. James M. Anders; *Vice-Presidents,* Drs. M. Howard Fussell, Albert M. Eaton, H. M. Christian, M. B. Hartzell, and Franklin Brady; *Secretary,* Dr. Wm. S. Wray; *Assistant Secretary,* Dr. Ross H. Skillern; *Treasurer,* Dr. Collier L. Bower. Reports were presented from Censors, Directors, Secretary, Treasurer, and Publication Committee. A resolution was adopted petitioning the Legislature of the State of Pennsylvania for an appropriation not less than $500,000 for the establishment of camps, sanatoria, hospitals, and dispensaries for the treatment of the tuberculous sick.

A New Medical Society.—Physicians of West Philadelphia have organized the West Philadelphia Medical Association, and have elected the following officers: *President,* Dr. A. F. Targett; *Vice-President,* Dr. George C. Shannon; *Recording Secretary,* Dr. Wm. D. Beacon; *Financial Secretary,* Dr. A. P. Good; *Treasurer,* Dr. J. D. Brittingham.

Medical Society of the Missouri Valley.—In response to an invitation from the Jackson County Medical Society, the semi-annual meeting of the Medical Society of the Missouri Valley will be held in Kansas City, Thursday, March 23, 1905. Those desirous of presenting papers should send their titles to the secretary not later than February 10. Papers will appear upon the program in the order in which they are received. A Symposium on Puerperal Fever will be one of the features of the session, opened by Dr. R. T. Sloan, of Kansas City. The president of the society is Dr. S. Grover Burnett, Kansas City, the secretary Dr. Chas. Wood Fassett, St. Joseph, Mo. Dr. C. Lester Hall of Kansas City is chairman of the arrangement committee.

Medical Club of Philadelphia. — At the annual meeting held January 13 the following officers were elected for the ensuing year: *President,* Dr. Roland G. Curtin; *First Vice-President,* Dr. Wharton Sinkler; *Second Vice-President,* Dr. Thomas G. Potter; *Secretary,* Dr. J. Gurney Taylor; *Treasurer,* Dr. Lewis H. Adler, Jr.

The Fifth International Congress of Psychology will be held at Rome, April 26-30, 1905. There are to be four sections: Experimental, Introspective, Pathological, and Criminal. The general secretary, Dr. Tamburini, may be addressed at 92 Via Depretis, Rome, Italy.

A Healthful Town.—The report of Drs. West and Patterson, Health Officers for Brookville, Ind., shows that during the past year not one case of smallpox, measles, mumps, scarlet fever, whooping cough, or chickenpox occurred in the entire city.

French Training School for Nurses.—A great field exists at present in France for lay trained nurses, owing to the suppression of the religious orders. Baronne James de Rothschild has established a school in Paris to teach young women everything essential to the duties of the trained nurse. Boarders and outside pupils are to be received and will be admitted to lectures at the hospitals, and granted diplomas.

An Unusual Suit.—Dr. Doyen of Paris is said to have instituted a suit for 200,000 francs damages against a company engaged in the production of cinematographic films. It appears that for some years Dr. Doyen has had his more important operations cinematographed with the object of recording his methods. The photographic concern did not regard their responsibilities in a scientific spirit, however, and several Parisian hostesses began to find cinematographed operations an agreeable diversion for after-dinner parties. The denouement may be imagined when one of the guests at such an affair witnessed her own operation thrown upon the screen. Dr. Doyen, after trying in every way to stop the display of the films, has brought suit, but the defendants assert that as they took the films they were free to use them as they pleased. A decision in the case has been deferred.

A Tuberculosis Directory.—A directory of American institutions dealing with tuberculosis has just been published jointly by the Charity Organization Society and the National Association for the Study and Prevention of Tuberculosis. It contains many statistics and much information which will serve as a guide to physicians and friends of consumptives.

Hospital News.—*The Sydenham Hospital, New York,* has just received, as a New Year gift, from Isaac Guggenheim, one thousand dollars. Mr. Guggenheim has also made a generous offer further to aid the hospital and its training school by giving monthly an amount of money equal to such sums

as the Board of Directors succeed in raising each month through donations or voluntary contributions. This offer holds good up to the sum of ten thousand dollars a year, should the Directors raise a like amount. The recent benefit entertainment at the New York Theatre netted the sum of fifteen hundred dollars for the Hospital. The Sydenham Hospital was started two years ago and has been very successful. At first only one building was used for its dispensary, but the work and the needs of the hospital grew so rapidly that to-day three buildings are thoroughly equipped for this purpose. After May next, the two adjoining buildings will be added to the hospital plant in order to provide more room for nurses and private patients, and when complete the hospital will occupy five buildings, Nos. 339 to 347 East 116th street. The last report of the hospital shows that more than ten thousand treatments were given at the hospital dispensary during the past year and six thousand hospital days were free in the hospital.

State Appropriations.—A bill has been introduced into the Pennsylvania Legislature looking to the appropriation for $300,000 for the Free Hospital for Poor Consumptives. Of this sum $100,000 is for maintenance of the sanatorium at White Haven, $100,000 to assist in the erection and equipment of new buildings to increase the capacity to as nearly 300 beds as possible, and $100,000 to assist in purchasing a site in a suitable location and the erection thereon of buildings for the care and treatment of persons suffering from tuberculosis at a more advanced stage than can be treated at White Haven.

Bequests.—In accordance with the adjudication of the estate of the late Selina Walker, of Philadelphia, the Jewish Foster Home and Orphan Asylum will receive $9,965.64, the Jewish Hospital Association $7,286.73, the Jewish Maternity Hospital $2,428.90.

Hospital for Alcoholics.—A bill has been introduced at Albany providing for the treatment of persons found incompetent from the use of alcoholic stimulants, opiates, narcotics, or other drugs. It directs New York City to provide a hospital with a competent staff for the treatment of such cases, the Mayor to appoint these physicians, who are to be paid out of excise funds. Commitment to the hospital shall be made on the sworn application of the father, mother, husband, wife, brother, sister, next friend or child of the patient or by city magistrates. It is understood that the new hospital would take the place of the alcoholic wards of Bellevue.

New Medical Ward for Cook County Hospital.—A ward, with 100 beds, will be opened at an early date at the Cook County, Ill., Hospital, as the Public Service Committee recently concurred in the report of the Hospital Committee that the old ward for contagious diseases be changed into a medical ward. It is estimated that the alterations will cost about $4,000.

The Presbyterian Hospital, Cincinnati, will close February 1, in spite of the efforts made to keep it open. No definite financial aid has been obtained for the coming year.. The Board of Medical Directors of the Cincinnati Hospital have agreed to take the nurses in course of training as fast as it is possible, so as to allow them to complete their course.

Rival Hospital Schemes in Greenwich, Conn.—The Medical Society of Greenwich, Conn., is in favor of spending $10,000 for the purpose of enlarging the present isolation plant, which contains a small emergency hospital, in order to provide the town with the hospital facilities that are needed. This is not in accord with the wishes of the local hospital association, backed by several wealthy New York men, who have raised $60,000 for the erection of a hospital, and are desirous of having the doctors turn over their $10,000 to the proposed $100,000 fund.

Obituary Notes. — Dr. Edward Valencourt Deuell, of Saratoga, N. Y., died suddenly on January 20, while in the witness chair in the trial of a case in the Supreme Court. He was sixty-five years old and was born at Malta, Saratoga county. He was educated at Union College, Schenectady, and was graduated with the degree of M. D. from the University of Louisville, Ky., in 1863. In that year he was appointed assistant surgeon in the Union Army, and at the capture of Little Rock, Ark., was placed in charge of the general army hospital. He was then appointed surgeon-in-chief of the District Arkansas and filled that post until 1869. Retiring from the army, he practiced his profession in Little Rock until 1889, when he removed to Saratoga.

Dr. Seth R. Beckwith died at Atlantic City, N. J., on January 20, at the age of seventy-two years. He was a graduate of the Homeopathic Hospital College, Cleveland, O., in the class of 1853. He was at one time President Garfield's family physician.

Dr. Leonard J. Gordon died at his home in Jersey City January 18. He was born in this city in 1844, and was a graduate of the Bellevue Hospital Medical School in the class of 1875. He was engaged in active practice only a few years.

Dr. Otis Eugene Hunt, of Newtonville, Mass., died on January 20. He was born in Sudbury in 1822. He was graduated at Berkshire Medical College in 1848 and continued in active practice until 1885.

Dr. Joseph Peltz died at Philadelphia on January 13, at the age of sixty-two years. He was graduated from the Medical Department of the University of Pennsylvania, in the class of 1865.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

THE KING'S HOSPITAL FUND—LORD MOUNT-STEPHEN'S MUNIFICENCE—STUDY OF GREEK—MR. S. COLERIDGE AGAIN, AND THE LONDON HOSPITAL'S INVESTMENT—CENTRAL MIDWIVES BOARD—THE DIRECTORY—NOTES—OBITUARY.

London, January 6, 1905.

Lord Mount-Stephen has signalized the new year by another magnificent gift to the King's Hospital Fund. Writing to the Prince of Wales as President, on the first of January, his Lordship expressed regret that the conditions of the anonymous offer failed, and enclosed an order for the delivery of bonds to his Royal Highness of the value of £200,000, producing an income of £11,000. The Prince showed the letter to the King and His Majesty at once wrote to Lord Mount-Stephen to express his "high appreciation of your magnificent donation," adding, "I have not forgotten that it is the second large donation which you have so kindly given, and I have now every hope that, owing to your great liberality, my fund will now be placed in the sound permanent position I had always hoped it would attain."

We have lately had some vigorous discussion, both at Oxford and Cambridge, on the question whether Greek should be a compulsory subject at the earlier examinations. The removal of Greek from the compulsory list is put forward by one party as a necessary concession to students who propose to devote themselves to science, and it was argued with more or less insistence that an elementary acquaintance with Greek was absolutely useless to scientific students and robbed them of a year or two's time, which could be more profitably spent in their more practical pursuits. The discussion found its way into the newspapers and called forth a correspondence, in which the statements were more fallacious than those of the heated university dons. In each arena we are confidently assured by some of the combatants that Greek requires some seven or eight years' study to be of any value; that those who intend to follow a scientific career are greatly hindered by trying to acquire the elements of the language;

that an elementary acquaintance with it is absolutely useless and not to be obtained concurrently with scientific studies, etc. On the other hand, these and many other assertions are as confidently denied by other disputants. If the scientists are really pressing these views on the universities they might at least remember that they still call on Greek to help them in their nomenclature, in which they inflict many sesquipedalian monstrosities on their readers. So far as medical literature is concerned, something similar might fairly be said. Really, it seems of more than exaggerational to talk of a little Greek as [illegible] the scientific student of precious time. That [illegible] could be acquired at school, or during the medical curriculum, and it would well repay the student by the help it afforded in understanding technical terms. Any examination in it should be restricted to the preliminary test, and be quite elementary. Even that "little"—pace the Dons—might have prevented the appearance in the *British Medical Journal*, during the last month, of three communications on "afebrile" enteric fever.

Mr. Stephen Coleridge is following up his attack on the Sunday Fund, in connection with the grant to the London Hospital, with the persistence in misstatements he usually displays. He asserted that the hospital had misappropriated its moneys by buying a cricket ground for the students. Mr. Holland explained that the ground had been purchased and let at a rental paying four per cent. per annum, that the security was as good as the one for which it was exchanged, and, in fact, that the property could be sold at a great advance on the price paid. Mr. Coleridge then reiterates that this is an unjustifiable diversion of the funds of the hospital, and complains of Mr. Holland's methods of controversy—a curious complaint from a man who has had to pay £2,000 as damages for the libellous method of controversy he has employed.

The subject would scarcely be worth notice had not the *Medical Press and Circular* taken it up in connection with its criticism of the Sunday Fund's attitude towards small special hospitals. That attitude certainly savors of injustice and prejudice, as I have more than once pointed out. I can, therefore, sympathize with the criticism in question, but it is not right to talk of the hospital "spending £6,000 on a sports ground for students," after it has been shown that this was no gift, but just as much an investment of the funds as would be the purchase of consols, only it yields a larger interest. The *Press* says: "The money was given for the benefit of the sick poor," but surely it will not be contended that the hospital ought not to have investments of any kind, but spend each year whatever it may receive.

The Central Midwives' Board's scheme of examinations has been sent back by the Privy Council, with the very proper intimation that examiners should be required to be qualified medical practitioners. Thus the absurdity of the women members who wanted to appoint midwives to report on the teaching of doctors, on the ground that these females could examine in bed-making, has been exposed to the public. It is becoming more and more obvious that it is necessary to impose a limit on the proceedings of the feminine party on the Central Board, unless the present rebuff brings them to their senses.

The medical directory for 1905 is out and the consequent shower of circulars has begun. The influx of new members of the profession continues and 572 additional names are added to the list. The total number now is 38,361.

What say you to this authentic instance as a proof of the value of physiology teaching in elementary schools? Inspector: "What is our blood composed of and how does alcohol act on it?" Answer: "It is made of one million red insects and one thousand white ones to every drop of blood. Alcohol kills them and sends their carcasses to the front of the body. That is why people who drink alcohol have red noses."

Dr. J. R. Wolfe, founder of the Glasgow Ophthalmic Hospital, and professor of ophthalmology in St. Mungo's College, died on the 26th ult., aged 80. He was M.D. Glas., 1856; F.R.C.S., Ed., 1868. His modification of the operation for cataract in detachment of the retina is well known and widely adopted. He retired from practice several years ago.

Liverpool loses two notable practitioners in Dr. James Armstrong, consulting physician to the Lying-in Hospital, who lost his life by a gun accident at a village where he was staying, and Dr. Adam, who was also away from home. He had been an invalid for some time and knew his precarious condition, but it seemed a surprise to his many friends when he died on the 19th ult., aged 38. He was on the committee of the Tropical School; he had had four years' experience on the West Coast of Africa.

Edward Treharne, J.P. for the county of Glamorgan, L.R.C.P., died very suddenly, on the 29th ult. [illegible]. He was a member of the Board of Health for the Pontypridd district, and had been its chairman.

OUR BERLIN LETTER.

(From Our Special Correspondent.)

BERLIN, DECEMBER 23, 1904.

POST-GRADUATE SCHOOLS UNDER GOVERNMENT CONTROL—OLD AGE AND INVALID INSURANCE—SENATOR'S SEVENTIETH BIRTHDAY—ALBUMINURIA—SYPHILIS IN A HORSE—HUMAN AND BOVINE TUBERCULOSIS—ORTH'S VISIT TO AMERICA—OBITUARY NOTES.

Again the German medical world with few exceptions is expressing its antagonism to the foundation of a government institution, namely, an academy of medicine, the purpose of which is to offer special post-graduate advantages to specialists. Plans for founding such institutions now exist in Cologne, Hamburg, Frankfort, and Dusseldorf. There are, however, already enough specialists in Germany. To offer facilities for increasing their number would make the existing conditions still harder for general practitioners. The number of post-graduate schools is already sufficient for the demand. In looking for the cause of this movement, it would seem due partly to the fact that the government needs places for the education of army physicians; partly that it purposes to confer upon these academies the privilege of granting diplomas to specialists; this would be a disadvantage to the present specialists. From any point of view, there would be no advantage to the German physicians, and the authority of our universities, which are our pride, would be made to suffer.

Another important medical question has been presented to the Reichstag. Its full importance is appreciated by our admirable secretary of state, Count Posadowsky. A motion has been made to found an old age and invalid insurance society for workmen. If this bill should be passed lodges would soon be founded which would greatly reduce the number of people applying for free medical treatment. Count Posadowsky warned against the insurance plan, for under it incentive for work would be lessened. It is impossible to make an insurance society of all Germany. The State advances when the individual saves for his own future.

Senator has lately celebrated his seventieth birthday. The Berlin physicians observed the event to show their pride in the remarkable work of this great man. On November 21 his paper "Ueber physiologische und pathologische Albuminurie" was read in the Verein für innere Medicin. He said that when individuals otherwise well, void albuminous urine after exercise, the condition is called functional or essential albuminuria. Albuminuria is physiological when following excessive exercise, especially of the lower extremities; after hearty meals consisting largely of albumen; during menstruation; after cold baths, sexual excess, and mental exertion. In other conditions, albuminuria is pathological. Orthostatic albuminuria is generally classed here. Two errors must be avoided: the ideas (1) that in every case of nephritis it is necessary to find casts, and (2) that chronic nephritis is incurable. Knowledge of the blood vessels is of the greatest importance in explaining the condition of albuminuria. This is clearly accomplished by P. Edel who has made careful investigations in this line.

It was an unusual sight that presented itself on December 7, in the sessions hall in the "Medicinische Gesellschaft." A carpet of straw was spread before the first row of seats and Piorkowsky showed a living horse that had been infected with syphilis. From 5 to 10 c.c. of blood had been taken from 80 syphilitic men and injected into the jugular vein of the horse. No primary effect was observed, but after four weeks an eruption developed over the whole body, together with swelling of the submaxillary and neighboring lymphatic glands. The histological appearance of the eruption resembled to a great extent that of lichen ruber. Kromayer offers the objection that in the man the eruption is not only in the cutis but exists also in the subcutaneous tissue. Benda and v. Hansemann did not consider the histological picture that of syphilis because it lacked the characteristic of this disease, viz., the early involvement of the intima of the vessels.

The annual meeting of the German tuberculosis society was most interesting. A state commission was appointed for the study of human and bovine tuberculosis. One of the investigators read a paper on human and bovine tuberculosis, in which he described the differences between the bacilli of human and those of bovine tuberculosis. Out of 56 cases he found 50 in which there were only bacilli of human tuberculosis. The other 6 patients were afflicted with tuberculous mesenteric glands (they were all children), and in these cases were found the bacilli of both human and bovine tuberculosis. The investigator could not transform one species into the other. Amusement was caused by the report that cows recently imported from Denmark had been treated on the border by the traders with tubercu-

lin injections by which they were thus made immune against the diagnostic doses given by the health officers.

Orth has recently given an account of his visit to America. He said that he did not take this trip for the sake of medical study, but to see the World's Fair. He calls the Americans very hospitable and says that they love their country and are very proud of it. They enjoy showing it to foreigners. A great many of the teachers there were pupils of Orth whom they honored not only for his own sake but also because he is the successor of Virchow. He saw only the eastern part of the country, but he admired the medical institutions. He calls attention to the sanitation of the hospitals, speaking especially of the ventilation in the Johns Hopkins and Mount Sinai hospitals. The advantages for theoretical work—the subject of his own studies—are somewhat superior to those for clinical work. The life of the students is more united than it is among German students. Hitherto American competition has been considered only from a commercial point of view, but the time has now come to consider it as a rival in scientific studies.

Two Berlin physicians of renown have recently died, one the pathologist, Langerhans, a pupil of Virchow and director of the pathological section in the Moabiter Krankenhaus. He died from a tuberculous infection. His manual was one of the few books that gained the approval of Virchow. The other was Kurt Freudenberg. Great praise was due to him for the amelioration of the condition of physicians. He also bent his energies to the improvement of the sanitation of the city of Berlin. His efforts met with great success.

THE ARMY CANTEEN.

To the Editor of the Medical Record:

Sir: In answer to several requests to give my views on the canteen question, I would say that it is hardly possible to write clearly on a subject invested with dense prejudice and ignorance and strange misconceptions. The very term "canteen" and "anti-canteen" are most stupid errors used largely to create prejudice. In reality there is no such thing as an "anti-canteen law." The canteens were not prohibited by the act of Congress, but remain the same. The only prohibition was the sale of intoxicating liquors on any military reservation, or in any building used for military purposes. Why this law should be stupidly interpreted as abolishing the canteen, or the post exchange, or the soldiers' club rooms, or any other means used to make the soldiers' life pleasant, is incomprehensible. Why partisans should talk so dogmatically about the act of Congress abolishing the canteen, and thus depriving the poor soldier of assembly rooms, can only be explained as an effort to create a sympathy, and have spirits sold again in these places. It was never the intention of Congress to break up or interfere with the canteen, but only to prevent the demoralizing saloon part of it. So great was the interest in the canteen, that over half a million dollars were appropriated to promote and make them attractive. Some of this money has already been used. The only medical question is this: "How far is the efficiency and usefulness of soldiers and officers promoted by saloons in the canteens?" or rather, the sale of intoxicating spirits, or drinks of any kind containing alcohol? Personal experience of officers in the service will vary largely with their own taste and sentiment, and no agreement can be reached from their varied opinions. To the medical and scientific men outside, it would appear that the army should be under the same strict and common-sense rules which govern the work on railroads and in large manufactures, and all business enterprises requiring nerve, brain force and physical vigor. The common-sense experience of business and professional men demand that the saloon and the sale of intoxicating liquors should be kept as far away from their business interests as possible. No one would think of opening a bar for the sale of pure liquors to railroad men or operatives in the factory for the purpose of promoting better work, and keeping down discontent among the operatives. It would appear that the army should be managed on the same principle, and that nothing which would diminish the value of the services of the men should be permitted, or even tolerated, no matter what it was. The real question has been obscured, and covered up by hysterical statements pro and con. If the army is determined that the use of alcohol is essential for the perfection of their work, and the vigor and usefulness of the troops, they will no doubt succeed in having the law repealed, but if the Government insists that the army and its management should conform to the highest business wisdom and judgment of the present, the law will be retained. The medical side of this subject is purely a hygienic one, and the army surgeon who imagines that he is more competent to decide on the merits of this question, assumes a knowledge and an experience compared with the well-settled principles of business, that sound very strange. There is no sentiment in this matter. Railroad corporations have reduced the facts of the influence of alcohol to dollars and cents. They know the losses which come from moderate drinkers in active service, and it is no sentiment to forbid the sale of spirits to their men, and discharge them if they persist in using it. It is a mistake to suppose that sentiment and theory could plan and carry out a measure of this kind unless it was supported by an experience and a common-sense conception of the reality. It is a mistake to suppose that sentiment can continue this law despite the judgment and experience of persons who differ with them. There is only one issue and that is, "shall license places be established for the sale of spirits to the soldiers in the army, or not?" It is not "canteen" or "anti-canteen," and most fortunately the final issue will not be reached from the opinions and theories of individuals. It will be settled as all other great subjects are, from a higher point of view, and along more exact lines.

T. D. Crothers, M.D.

Hartford, Conn.

A CASE OF CRYPTORCHIDISM.

To the Editor of the Medical Record:

Sir: In a recent issue of the Medical Record, a case of cryptorchidism is reported which contains a singular statement against which I protest as an instance of careless and unscientific misstatement. Among other things, the author writes: "This case from a medicolegal aspect is not without interest. In searching the literature of the subject at my command, I find that all authorities agree that cryptorchids are sterile. Doctor Curling (*British and Foreign Medical and Surgical Review*, April, 1864), has narrated nine cases in which the ejaculated semen of men with retained testes, or with a single testis, the other having been removed or its duct obstructed, was destitute of spermatozoa. The history of the case certainly contradicts the foregoing, for the patient is the father of a child whose resemblance to him is marked." This statement against the experience of all competent observers is made without the slightest evidence being adduced to show that an examination of the semen of this fertile cryptorchid had ever been made. Every authority agrees that whenever the semen of genuine cryptorchids has been examined the absence of spermatozoa has always been marked, notwithstanding the fact that some of these cryptorchids were said to have been fathers of children.

My only reason for commenting upon this case is to protest against the careless manner in which medical cases are so frequently reported, which not only makes them of no value for either clinical or scientific purposes, but, if taken seriously, renders them misleading.

F. R. Sturgis, M.D.

New York.

The Necessity for a Periodical Examination of the Apparently Healthy.—Alexander MacKenzie Campbell emphasizes the importance of preventive medicine. He divides society into three classes: The perfectly healthy, the apparently healthy, the unhealthy. The number of individuals who have no subjective reason to believe that they are diseased, but who, on examination, are found to be in the third class, is very large. The writer cites several cases which have fallen under his own observation, who, for one reason or another, on presenting themselves for examination, have been found to be suffering from serious lesions hitherto unsuspected. The following order in the physical examination has been suggested: Examination of the respiratory, circulatory, digestive, and urinary apparatus, and, finally, examination of the nervous system. The writer recapitulates as follows: Physicians have a tremendous responsibility in keeping people well. Only a small percentage of people enjoy perfect health. Physicians should educate people in apparent health to the necessity of subjecting themselves to a periodical physical examination. This examination, made at least yearly, should be careful and systematic, and should embrace all of the approved chemical and microscopical tests for the diagnosis of disease.—*Detroit Medical Journal.*

The "Atlantis" of this city, the first newspaper in the Greek language published in the United States, is henceforth to be issued daily. It was founded twelve years ago as a weekly; subsequently it became a semi-weekly, and then a tri-weekly, and now will be issued every day, owing to the increase of the Greek population here.

Progress of Medical Science.

The Boston Medical and Surgical Journal, January 19, 1905.

The Humane Treatment of Malignant Disease from a Surgical Point of View.—John C. Munro here presents a plea for more frequent interference in incurable malignant disease. He himself, as time goes by, becomes more and more willing to operate in cases in which there is the smallest outlook for relief. In dealing with cancer, neither surgery nor any other form of treatment is yet able to assure permanent relief in more than a small percentage of cases. Surgical cure depends upon the locality of the growth and upon the stage at which the operation takes place. The writer believes that there are enough desperate cases only temporarily relieved by operation to make it not only worth while, but also a duty to hold out these chances to such patients. Unless the surgeon can absolutely and definitely make a diagnosis of inoperable malignancy, especially when dealing with the abdominal cavity, it is safer to explore for absolute confirmation. And when the diagnosis can be made which condemns the patient to death, then most of all, exploration should be made. However, to operate for diagnosis without first using all other means is wrong, and ought to be condemned. The writer cites certain cases in which the diagnosis of malignant disease was proved by operation to be wrong. On the other hand, many cases of unquestionable malignant disease have been entirely relieved by operation of distress and suffering, and this for weeks and months until death came quietly from a general malignant toxemia, a state of affairs which would have been impossible without the operation. In regard to cancer of the intestine, the writer believes that we should be very conservative in committing such cases to medical treatment. In 43 cases of cancer of the rectum, Czerny lost only 3 by operation, the remaining 40 living from 40 days to 3½ years. In cases of cancer of the colon there is a quiescent period between the appearance of the first symptoms and the last fatal issue. It is inhuman to remain inert during this period. In Nothnagel's last edition, it is stated that the only way to arrive at a positive diagnosis in abdominal cases with indefinite symptoms is to perform an exploratory laparotomy. Surgery is indicated at the earliest stage. Cancer, wherever situated, is a surgical disease. The action of the Coley serum is still too uncertain for employment except in cases beyond surgery. The writer believes also that the *x*-ray is already doing more harm than good, except in very limited types. The writer appeals to the surgeon for more optimism in dealing with the apparently hopeless cases.

A Brief Consideration of Some of the Results of the Surgical Treatment of Cancer of the Stomach.—R. H. Fitz gives briefly the results of operation on 37 patients whose records are taken from the files of the Massachusetts General Hospital and also from Munro's communication to the Massachusetts Medical Society, June, 1904. Of these 37 patients, suffering with cancer of the stomach, 28 died within 2 months after operation, and only 1 is stated to have been in good condition at the end of 12 months. The writer declares that equally good, if not better, results are known to follow the medical treatment of such cases. From these cases, it would appear that merely exploratory operations in advanced malignant disease involving the stomach have a considerable mortality, afford no relief, and are followed by an early death. In the survivors, relief is inconstant though sometimes prolonged at least a year. Surgical treatment of advanced cases of malignant disease of the stomach may be said to be humane because it sometimes gives relief, more or less prolonged, and often shortens the period of suffering even if it gives no considerable relief. On the other hand, the treatment of such cases by other than surgical methods often gives more or less prolonged relief and usually makes dying easy. The writer concludes by saying that should the choice lie between the two methods—surgical treatment, or the administration of a lethal dose—the latter has certain advantages in its favor.

The Brown Tail Moth Eruption.—Harvey P. Towle, in discussing this subject, gives a brief consideration of the life history of the brown tail moth. The caterpillar is hatched in late July. It molts twice in this season and in September builds its nest and goes into winter quarters. With the return of warm weather, it wakens into activity. In the latter part of May it molts for the third time, and for the fourth time early in June. It is at this time, that of the third and fourth moltings, that the short barbed hairs are found. It is at the same time that the eruption is prevalent. Various extracts have been made from the hairs, cocoons and molted skins, but no poison has been found. Unfiltered extracts caused an irritation of the skin in every case. Filtered extracts did not irritate. A bit of skin that had been irritated by a brown tail moth was excised and examined microscopically. In the lesions the same minute barbed hairs as those of the caterpillar were found beneath the epidermis. Thus it has been proved that the short barbed hairs of the brown tail moth cause an eruption in human beings as a result of mechanical irritation which is typical in aspect, very annoying, and one which in invalids or very sensitive people may be followed by serious consequences on account of the intolerable itching and consequent nervous strain.

New York Medical Journal, January 21, 1905.

On Rubidium Salts with Special Reference to the Use of Rubidium Iodide in Optic Atrophy.—P. Bartholon gives a brief account of the chemistry of the rubidium salts. The iodide has been used chiefly in syphilis as a substitute for potassium iodide when the latter was not well borne and in cases of heart disease. The author finds that a five per cent. solution in distilled water is non-irritating, highly diffusible, withdraws water from the circulation, and causes a vigorous movement of the red cells toward the site of application and that there is a marked chemical activity of the ions of rubidium and iodine freed by the dissociative force of the aqueous solution. The latter may be painlessly applied. The author has employed it in this manner in one case—that of a man with tabes, suffering from concentric diminution of the visual field with progressive loss of sharpness of vision. The results after a three weeks' use of the remedy were distinctly noticeable in the way of improvement. The author is not unmindful of the fact that sudden changes for the better sometimes come spontaneously in the group of symptoms mentioned, but he is inclined to give the rubidium salt a share of the credit and to persevere in its employment with the hope of defining its positive action.

The Vasodilators and Constrictors.—G. W. Greene gives his experience with this class of remedies. He finds that in cases of cardiac insufficiency with dyspnea and dropsy of the feet without valvular trouble, that the nitrites, especially nitrite of sodium, are most efficient, in that they relieve the heart by dilating the capillaries, thus lightening the load and giving the heart less work to do. He also commends the use of the nitrites in headache attacks, in which the patient is pale, while in the congestive type of attack, ergot is the drug indicated. In cases of arteriosclerosis or cirrhotic kidney, two grains of the nitrate may be combined with one one-hundredth of a grain of bichloride. He also believes that the nitrate is also of service in anemia. It dilates the arterioles and hastens the elimination of the waste material. This waste material contracts the arterioles, which hinder the elimination and thus keep up a vicious circle, which can be completely counteracted by vasodilators. In pneumonia, the author counsels the use of veratrum to soften the pulse, and when in two or three days the heart begins to fail he gives alcohol and strychnine. He advocates the injection after minims of solution of nitroglycerine in puerperal eclampsia. Finally, as a prophylactic in chlorform inhalation, he advises the injection into a vein of ten minims of adrenalin solution in order to avert death from extreme vascular dilatation.

Delayed Results of a Wound of the Brain.—P. O'Hanlon relates the case of a man who received a pistol shot wound in the temporal bone. It was treated as a mere scalp injury and the man was allowed to go about. In two months he began to have attacks of "fits" and finally was brought to a hospital, where he died, the diagnosis being brain abscess. Autopsy revealed a bullet resting beneath the anterior lobe of the right hemisphere at the base, to all purposes a harmless foreign body so far as the lead itself was concerned. The track of this bullet was plainly visible through the brain tissue, beginning at the left temporal lobe and passing across to where it was found. An examination of that part of the brain broken down into an abscess showed a small piece of lead, to which adhered a sharp piece of bone, which had set up the irritation which resulted in the formation of the abscess. Eighteen months had elapsed between the shooting and the autopsy. A skiagram taken before death located the bullet in the locality revealed by the autopsy.

Medical News, January 21, 1905.

The Cystoscope as an Aid in Genito-Urinary Surgery.—Follen Cabot declares that cystoscopy will never become an easily accomplished method of examination. Large experience, great patience, and plenty of time are essential in its practice. The operator should have excellent eyesight, and his perception of color should be perfect. The hand of the operator should be steady, and all unnecessary movements should be avoided. In many cases, a 1% solution of cocaine gives great comfort. The writer introduces about one-half ounce into the bladder, and places a little in the deep urethra as the catheter is withdrawn. He has found the direct view instrument the easiest to handle, but he believes that the indirect view or angular instrument should be understood by every one who does much of this work. The angular and retrograde telescope is necessary for the

examination of the prostatic region, while the straight-view telescope seems better for ureter catheterization. The bladder should be filled with about the same amount of fluid at each examination, for this organ varies in color and general appearance under varying amounts of fluid. The bladder can generally hold about 6 or 8 ounces. Great care should be taken not to overdistend the bladder, as rupture of this organ is possible. The patient should be made as comfortable as possible, while at the same time the ureteral openings and other parts of the bladder must be brought into view. The cystoscope is sometimes of use in detecting encysted stone of the bladder, stone in diverticula or in sacculations, and in other instances in which litholopaxy has been performed. This instrument is often of use in detecting new growths in the bladder. The writer has seen several new growths of the kidney. The cystoscope has not been of much help to the writer in determining the size of the prostate or the presence of a so-called third lobe. In one case of a suprapubic prostatectomy the cystoscope enabled him to diagnose a diverticulum which held eight ounces and had been caused by years of straining. This instrument is often helpful in locating foreign bodies in the bladder, especially in the female. The writer has devised a forceps for this work, and also a curette for removing a piece of cystic new growth for microscopical examination. The writer believes that the dangers of the cystoscope have been much magnified. It should, however, be used in selected cases and with careful technique.

Report of a Case of Postdiphtheritic Paralysis.—William J. Butler first gives a brief résumé of the literature in regard to the various changes observed during the course of acute infections and subsequent thereto. He then describes a case of postdiphtheritic paralysis of unusual extent, involving the external recti of the eyes, the soft palate, the pharynx, the abductors of the larynx, the diaphragm, and peripheral nerves. There was also acute cardiac dilatation, with pulmonary hypostasis, and edema; also liver stasis. During the subsequent course of this affection, it was noted that after withdrawal of the codeine and strychnine for 16 or 18 hours, a previous improvement in the cardiac condition was replaced by a condition approaching its earlier stages, and moreover, that a prompt improvement followed the resumption of medication. If either drug had this influence upon the heart, strychnine was probably the one. The writer states that it is probable that the dilatation was due to a change in the myocardium, that is, an acute myocarditis, concurring in Romberg's statement that all cases of diphtheritic heart paralysis present changes of acute myocarditis. The clinical picture of these cases varies according as the changes in the myocardium or in the vagus predominate.

American Medicine, January 21, 1905.

Psychiatry in Its Relation to Other Sciences.—Charles L. Dana shows the relations of psychiatry to its nearest allied sciences,—economics, psychology, physics, neurology and internal medicine, pathology and physiologic chemistry, criminology, forensic or legal medicine, and antropology. He indicates the lines along which work can be carried with mutual help to all, and especially to the advancement of a sounder knowledge of that capstone of all medical sciences, the pathology of the mind.

Subnormal Accommodation and Premature Presbyopia.—George M. Gould believes many failures to cure eyestrain diseases are due to non-recognition of insufficient or paretic accommodation, or premature presbyopia. He reports illustrative cases in which the clinical histories dated back from 6 to 14 years. From a careful study of these cases he concludes: (1) Subnormal, paretic, or insufficient accommodation, or premature presbyopia, even paralysis of the accommodation, of a functional or reflex nature, not dependent upon organic disease, exists in a certain, probably much larger than suspected, proportion of young or middle-aged persons. (2) It is usually permanent or ingravescent. (3) It may be caused by such degrees and kinds of ametropia as compel the renunciation of the accommodative function, especially high hyperopia or astigmatism, etc.; monocularity; glare of footlights; the use of magnifying glasses in engraving, etc.; long-continued abuse of the eyes; a direct inhibiting reflex to the accommodational mechanism. (4) It is of all degrees and varieties, and may even differ in amount in the two eyes. (5) It may complicate the condition of head tilting, torticollis, etc., with secondary spinal curvature, due to a peculiar axis of astigmatism in the dominant eye. The pathogenic results of dextrocularity and sinistrocularity should not be forgotten. (6) The pathognomonic symptoms are the persistence of common eyestrain reflexes (such as migraine, headache, indigestion, intestinal fermentation, constipation, nervous disorders, dermatoses, etc.) after proper correction of the ametropia and muscle imbalance, and especially an inability to carry on continuous nearwork. (7) The diagnosis is impossible by any of the ordinary tests. The loss of power has come on so slowly or has been so long present that the patients have no suspicion that the print is not clear, and it is usually possible for them to read even the finest letters with ease, and for a short time. The comparative rarity of the cases also throws the oculist off his guard, and routine begets carelessness. Abnormally wide pupils of one or both eyes, the demand of high corrections for distant vision, certain occupations, certain forms of ametropia and anisometropia, high heterophoria, unrelieved reflexes, photophobia, etc., are suggestions that there may be accommodation weakness. (8) It is an active cause of heterophoria, adding to the proof of the common dependence of muscle imbalance upon ametropic and optical causes. (9) The treatment is by means of bifocal spectacles, which accurately neutralize the error of refraction for distant, and the deficiency in accommodational power for near vision. Success depends upon the amount of damage done before the appropriate therapeutic measure is found. Usually relief is sudden and striking.

Is Cesarean Section Ever Justifiable in the Management of Placenta Prævia?—Richard Douglas estimates the dangers that attend cesarean section in the management of placenta prævia and limits it to placenta prævia centralis in primiparæ with undilatable cervix. An exsanguinated patient or one that has been subjected to various obstetric manipulations, repeated efforts at dilatation or version, thus opening the channel of infection, are not subjects for operation. In the execution of the operation, the surgeon must not forget his surgical training. There should be time for the uterus to contract and retract after the removal of the child. If this precaution is taken, there need be no fear of hemorrhage from the placental site. Should it occur, our means of controlling it are infinitely superior to what they would be after delivery by the natural channel. The cervix is easily torn in the presence of placenta prævia—an accident that is not always discovered at the time, and only recognized by its disastrous consequences. Remembering that labor is usually premature in placenta prævia and that the mortality of premature children is very high, this operation should not be undertaken in the interest of the child alone.

Radiotherapeutic Nihilism.—G. G. Burdick believes the destructive effects noted in the various malignant conditions are due solely to the chemical ray, and in order to get the best results the degree of penetration should be controlled in order to allow the ray to come to rest in the tissue where results are desired. He states that: (1) in lupus and local tuberculosis the tube should be held within four inchs of the skin, and the penetration regulated to within a half inch, in order to take advantage of the ray of low velocity that resembles the cathode rays; (2) in carcinoma and epithelioma the tube should be at 10 inches, and the penetration calculated to about the center of the growth, producing irritation at least twice and then increasing the degree of irritation to a high velocity, in order to get a cellular degeneration; (3) sarcoma requires a very high degree of penetration, depending upon the density of the growth; (4) when a lethal effect on tissue is desired a very low tube should be used; (5) the lethal effects are due to the chemic radiations; (6) the tonic effects are due to the fluorescence of the ray, fluorescence being understood as a form of motion; (7) all unbroken carcinomas should be thoroughly rayed before operation.

Journal of the American Medical Association, Jan. 21, 1905.

Dengue in the Isthmian Canal Zone.—This paper is a narrative of the personal experiences of D. N. Carpenter and R. L. Sutton, who have paid particular attention to blood examinations in dengue cases. Their findings are summarized as follows: (1) Dengue is one of the few fevers in which a leucopenia persists from the first. (2) Blood examinations are of great value in differentiating between malaria and dengue. Even though no parasites be found, a slight leucocytosis, with decided increase in the percentage of large mononuclears and transitionals is indicative of the former, while a leucopenia, with a normal differential leucocytic count or varying degrees of a small mononuclear lymphocytosis and a marked eosinophilia late in the disease, is characteristic of the latter. (3) Albuminuria is seldom seen in an ordinary attack of dengue, and then only in small amounts. The exact opposite is true of yellow fever. (4) The period of convalescence in dengue is almost invariably ushered in by a pronounced small mononuclear lymphocytosis, which persists for several days. (5) It is suggested that the causative agent is a small diplococcus or a delicate bipolar staining bacillus closely resembling Pfeiffer's organism. It is probably transmitted by the respiratory tract, and its virulence is much increased by the presence of the essential meteorologic factors and by overcrowding.

The Mechanism of Streptococcus Infection.—G. F. Rendiger finds that leucocytic exudate, the cell-fire exudate, and suspension of leucocytes or of bone marrow in serum or

in defibrinated blood kill non-virulent but not virulent streptococci. Suspensions of organ cells from guinea pigs in serum or defibrinated blood do not kill streptococci. Leucocytes in the living animal take up streptococci. The author believes that we are warranted in concluding that the leucocytes and the bone marrow are the most important (if not the only) factors concerned in combating streptococcus infections in rabbits and in guinea pigs. It has been shown that normal human serum is a good culture medium for streptococci, and that there is active phagocytosis of streptococci by the leucocytes in a case of streptococcus infection in man. It would seem, therefore, that in man also the leucocytes are an important factor in protecting the body against invasion by streptococci. It has also been shown that the leucocytes take up living streptococci *in vivo*, and in all probability destroy them, but the fact that the cell-free exudate also destroys many organisms indicates that there may be destruction of cocci extracellularly as well as intracellularly. Virulent streptococci, when grown in heated serum, secrete a substance which is toxic for leucocytes. This may throw some light on the question why virulent streptococci are not taken up by the phagocytes. The practical value of this demonstration is self-evident. If we accept the view that the leucocytes are the most important agent in combating streptococcus infections, we see at once that the destruction of these cells by the toxin, as they collect about the focus of infection, robs the body of its strongest defence against these organisms.

The Lancet, January 7, 1905.

Recurrent Effusion into the Knee-Joint after Injury.—W. H. Bennett's paper is based on a series of 750 cases. Of these, the symptoms of internal derangement were precise in 428, the symptoms from lesions of the outer side of the joint being less acute than those from lesions of the inner side. In the former instance, when the semilunar cartilage was at fault, pain and locking were referred in half the cases to popliteal space; 56 cases presented no other symptoms than mere recurrence of the effusion, without noticeable further injury; 24 presented loose bodies in the joint; 4 were cases of genu valgum. Two hundred and forty-one cases were influenced by constitutional conditions. Of these, 107 presented conditions of osteoarthritis, 30 of rheumatism and gout, 42 of syphilis, 28 of gonorrheal rheumatism, 18 of malaria, 3 of hemaphilia, and 13 of what the author calls "quiet effusion in young people." He finds this condition in the knee (and ankle) joints in young girls during adolescence if menstruation is irregular, and especially when its onset is delayed. Its regular establishment is generally followed by a disappearance of the joint trouble. Operation was called for in 87 instances. In case both semilunar cartilages are detached as a result of injury, the author advocates the making of the exploratory incision on the inner side

The Cultivation of Trypanosoma Out of the Leishman-Donovan Body after Rogers' Method.—The patient whose blood was examined by G. C. Chatterjee was a man who had had fever for six months, with enlarged spleen, the blood being taken by puncture from the latter organ. Three or four of the L.-D. bodies were found in each microscopic field, and on culture they reproduced rapidly. On the third day all stages of transition were seen from an L.-D. body to a fully trypanosoma-like body. The fully developed organisms of the latter type were characterized by the following peculiarities: (1) The position of the micronucleus at the anterior end of the body of the parasites; (2) the long, thick anterior flagellum; (3) the absence of, or, if present, rudimentary—undulating membrane, and (4) the rudimentary posterior flagellum. On account of the presence of these characters, they would appear to be less closely allied to the class trypanosomidæ, such as trypanosoma Brucei and trypanosoma Evansi, than to the class of trypanopis described by Keysselitz, which is characterized by the possession of a micronucleus at the anterior end, a long, thick anterior flagellum taking its origin from the micronucleus, a rudimentary, undulating membrane and a hardly discernible posterior flagellum, which takes no part in the movement of the parasite. A well-executed colored plate accompanies the article.

Child Study and the Treatment of Paralysis in Children.—A. A. Mumford notes that there are a number of crippled children with congenital spastic paraplegia who show an irregular or abnormal progression which is very instructive in any analysis of the movements of the limbs. Owing to the disturbances in the motor tracts, leg spasm occurs in the predominating muscle groups, such as the abductors and internal rotators, while paralysis involves the abductors and external rotators. Concomitant features are listlessness, apathy, defective speech and mental deficiency. If by the time the child is six or eight years old, he has of himself acquired sufficient muscular coordination to be able to get about on crutches somewhat, pedic procedure will provide a more or less satisfactory limb. The author analyzes the process of learning to walk, the child gradually exchanging spontaneous and amilers for voluntary and purposive movements. Their coordination is educated by kicking against the bed, etc., whereby the muscular and tactile senses are developed. By the sixth month the child exhibits sufficient pleasure in organized muscular action to enjoy pushing his feet against the floor when the attendant holds the body and allows the feet to dangle; and by the ninth or tenth month rhythmic movements of extension and flexion take place in the two legs alternately. These early movements, which are precursory to walking, seem to be partially reflex in character. Though the child cannot actually walk or stand he has already gained considerable control over the movements by which he will presently be able to do so. Another element is standing—viz., balancing of the head and trunk—is next acquired. At first the child calls to his aid the hands and arms and bal ances himself by grasping his mother's dress or some other object. This is half way to bi-pedal progression. The position of the feet at this stage of learning is very char acteristic. The legs are separated and widely apart, the toes are turned inwards, and there is a vigorous flexion of the great toe and the digits so that the feet seem to be actually gripping the floor. This stage is generally acquired by the twelfth month. The author's main contention is that by very simple apparatus and muscular exercises intelligently performed on children, all based on the principles found to obtain in the normal development of the power to walk, will afford great benefit to the class of patients suggested by the title of his paper. Diagrams illustrate the various points made.

British Medical Journal, January 7, 1905.

Soft Fibroma of the Larynx and Neck, Removed by External Operation Without Opening the Cavity of the Larynx.—Felix Semon reports this unusual case. The patient was a married woman aged 40 years. The writer first saw her in 1898. Up to 1888 she had enjoyed good health, except that she had sometimes suffered from slight "spasms" in the throat. These seem to have preceded all objective phenomena related to the throat trouble. In 1888 she first observed a swelling in the left submaxillary region. This gradually grew, till in 1898 it was as large as an average walnut. At first it produced no discomfort, not causing any difficulty in breathing or any disturbance in the voice. In the spring and fall it used to swell, but always returned to its previous size. Little by little it became tender on pressure, and the patient's breath became permanently short. The "spasms" increased in severity. She consulted several physicians, and attempts were made to remove the growth, but without success. Finally, on account of difficulty in breathing, tracheotomy had to be performed. This gave great relief. Before this operation the patient had grown very thin, but after it was performed her general health improved. Shortly before the writer saw her the external swelling had increased in size, and there was a great deal of shooting pain in the throat, extending to the jaws and to both ears. Examination showed the external tumor to be tender to the touch, and any pressure on it, unless extremely gentle, caused immediate retching and coughing. It was not adherent to the skin and was somewhat mobile in various directions, although it seemed to be fixed to something very low down. The neighboring glands were not enlarged. Laryngoscopic examination revealed a surprising state of affairs. Although the voice was almost normal, there was present an enormous tumefaction of the left half of the larynx, which in front extended to nearly the free border of the epiglottis, and behind to the left arytenoid cartilage. All the corresponding parts of the larynx within that region seemed to have been absorbed into this smooth, round tumefaction, which was covered by apparently normal but very pale mucous membrane. Not much more than the free border of the epiglottis could be seen, and it was so twisted that the epiglottis looked towards the right. Neither of the vocal cords could be seen, and it could be concluded from the integrity of the voice that the left vocal cord itself could not be involved in the process. The right arytenoid cartilage moved well. The left half of the larynx was almost immovable. On touching the tumefaction with a probe there was a feeling of elastic resistance similar to that experienced on pressing upon the external tumor. The patient refused operation until in the early part of 1904, when her symptoms had become more severe. There was running from the eyes, inflammation of the conjunctiva, and very much increased salivation. The internal tumor had greatly increased in size, although the external one was not much larger. The writer, at operation, cut down upon the external tumor, dissected it out from its vicinity, and found at its distal end a thin, partly thread-like pedicle, which he followed up as far as possible. The tumor was extremely friable and broke into several pieces, which were removed without difficulty. The internal tumor was

shelled out by means of the finger. The tracheal tube, which the patient had worn for nearly 13 years, was removed. The patient made a complete recovery. The structure of the tumor proved to be fairly uniform and typical of a soft fibroma. It was edematous in character. This explained the fact that the tumor varied in size from time to time. Whether the growth began in the larynx or in the tissues of the neck has not been determined. From this case it is clear that pure fibromata may simultaneously involve the larynx and the neighboring parts of the neck. The close proximity of the growth to the superior laryngeal nerve explains the coughing and retching. The epiphora and salivation were probably due to the irritation of the sympathetic.

Ambidexterity.—N. Bishop Harman first reviews a number of morphological facts in relation to visceral asymmetry in human beings. He then advances an hypothesis as to the presence of a general right-handedness in man. He suggests an incident in the life of primitive man in which two of these beings have a hand to hand conflict. One learns the secret of division of labor in the fore-limbs, and uses his left arm for a shield and his right for fighting. He is the victor in the fight, and his offspring, after he has captured the wife of the victim, would revert to the maternal custom of using the left hand. The writer then cites various examples to prove the real ambidexterity of ordinarily trained men. Instead of ambidexterity, it might better be called coordination of bimanual action. Most men brush the hair with a pair of brushes, using each hand equally and coincidently in the task. Women plait the hair using both hands; they also hold the hand-glass first with one hand, then with the other, while adjusting plaits, coils and pins with the free hand. The process shows extraordinary bimanual dexterity, with hand and eye cerebration. Violin playing illustrates in a most remarkable way the division of labor between the forelimbs. The use of the typewriter and the inscription of the Braille type by the blind all show a wonderful bimanual division of labor. The writer concludes that the aim of the Ambidextral Culture Society is futile, for Nature has already done the work which this society proposes. In a long course of evolution, Nature has shown that it is desirable to specialize in the use of the limbs.

The Value of Nitroglycerin in the Practice of Surgery.—Frank Elvy cites two cases in which the use of nitroglycerin proved most valuable. The first patient gave a history of a rough life, hard drinking, together with "bad kidneys." The pulse showed high tension. The dorsum of the hand was swollen and edematous, the result, so the patient stated, of three small spark wounds. The condition of the hand becoming worse, several incisions were made on the dorsum, followed by fomentations. Strychnine and stimulants were administered throughout. The patient steadily grew worse. The wounds gaped widely, revealing a dry surface covered with dirty-looking sloughs. The condition appeared to be a typical moist gangrene. The patient refused amputation. Nitroglycerin, 1-100 grain, was given at 9 P. M. Vast improvement was apparent on the following morning. The radial pulse, which could not be felt the day before, was now restored on the affected side. The wounds no longer gaped, and they discharged freely a healthy-looking pus. Recovery was complete. Another patient, a Chinaman, who was suffering with a carbuncle on his neck, was treated by crucial incision and scraping under ether. The wound did not heal and was covered with a dry, yellow slough, and the neighboring tissues were swollen and indurated. Nitroglycerin was followed by the same successful results in this case as in the last one described. The action of this drug can be measured by the finger at the radial pulse while one notes the local effect upon a diseased part. Not only in incipient senile gangrene, but in all cases of impaired circulation in which contracted arterial walls are present, nitroglycerin should be of great value to the surgeon.

Berliner klinische Wochenschrift, January 2, 1905.

Infantile Scurvy in Berlin.—Neumann attributes the increase in Berlow's disease that has been noted in Berlin during recent years to the fact that many of the large dairies are pasteurizing their milk before delivery. Formerly this was done only in the case of special milk supplied to the better classes, but of late it has been found advantageous to subject a large share of the general supply to this process. In consequence, as many mothers subject the milk to another boiling after receiving it, the milk is frequently exposed to so much heating that it becomes the cause of disorders of nutrition in infants. Milk, even though pasteurized, that is vended in the streets, is exposed to so much risk of contamination that it should be boiled before use, and it is then likely to be unfit food. If the milk has not been pasteurized there is no objection to boiling it, and pasteurized milk delivered in bottles does not require boiling. The consumers should therefore be informed whether or not the milk has been subjected to a preliminary heating, and if so, to what degree this has been carried. Without this knowledge the consumer cannot determine the treatment the product should receive before use, and there is more or less danger of malnutrition to the infant. The author recommends that it be made compulsory for milk producers to indicate the fact when milk has been pasteurized.

The Nature of Urticaria.—Baum found that the application of ethylen glykol to the healthy skin that had been deprived of its superficial epithelium by rubbing with sand paper, gave rise to a localized edematous swelling in all respects similar to that of urticaria and lasting from fifteen to thirty minutes. In order to gain a better insight into the nature of this swelling he applied the same substance to the web of the frog's foot and was able to watch the formation of the wheal under the microscope. The phenomenon appeared to be a rapidly appearing and subsiding localized edema following temporary dilatation of the capillaries. There was no constriction of the veins, so that Unna's hypothesis to the effect that the lesions of urticaria depend on a spasm of the veins which gives rise to a localized congestive edema does not seem justified. The similarity between this artificial lesion and that of urticaria is still further borne out by the fact that only certain frogs show the phenomenon. Freshly-caught animals do not react in this way to the application of ethylen glykol, whereas those that have been kept in captivity over the winter invariably do, which is in accord with the personal idiosyncrasy observed in urticaria patients.

Münchener medizinische Wochenschrift, January 3, 1905.

Endemic Occurrence of Myelogenous Leukemia.—Arnsperger observed three cases of typical myelogenous leukemia which all came from the same district, and on making an investigation of this region, found that eight others existed or had recently died in this neighborhood. Pforzheim is the largest town of the section in question, and the cases came from there or from adjoining villages scattered along the Enz valley. The endemic occurrence of leukemia in this manner has not yet been described, and the author was unable to discover any explanation of the pathogenesis of the present series of cases. The list of patients comprised five women, four men and two children. Heredity does not appear to enter into the question, but the hygienic conditions were all of the poorest and the water supply is bad. The same district has suffered from several epidemics of typhoid fever. The occurrence of a number of similar cases in a restricted section seems to the author to point somewhat to a parasitic origin of the disease.

The Treatment of Exophthalmic Goitre with Antithyroidin.—Thienger and Hempel both discuss this subject and each author comes to conclusions favorable to the mode of treatment. Thienger treated four patients with tablets of antithyroidin made of the serum of sheep from which the thyroid gland had been removed about six weeks before the first bleeding. The average dose was 5g. of the serum by the mouth, every other day. In one case the treatment was apparently without effect, but in the other three very marked subjective and objective improvement followed. The body weight increased, the pulse rate dropped and in one instance there was a marked decrease in the size of the goitre, and disappearance of the exophthalmos. Hempel's case was also greatly improved by the use of 90g. of serum given in sixteen doses. That the amelioration was due to the medication was shown by the fact that when the tablets were omitted for two weeks the pulse increased in frequency and dropped again when the drug was resumed. Both authors concur in stating that the value of this form of treatment is still undecided, but that it promises well and deserves investigation.

A Case of Traumatic Pulmonary Hernia.—Cahen observed in a patient under his care the gradual development of a pulmonary hernia following trauma. The patient, a man of forty, was hit by a falling packing case which struck his right shoulder and forced his chest against a wall. The immediate results of the accident were those incident to the contusion of the shoulder, but four weeks later it was discovered that when the patient stooped over, a swelling the size of a hen's egg made its appearance in the first interspace close to the sternum, and extended upward and downward over the clavicle and second rib. On assuming the erect position the swelling disappeared spontaneously. The hernia could also be protruded by forcible expiration, with closed glottis. The nature of the hernia was determined by its resonance, the fact that exploratory puncture was negative, and by the further observation of a tendency to incarceration which developed itself after a time. The mass could then be returned to the thoracic cavity by manipulation and the fingers could detect crepitation as this was done. After a while the hernia always became incarcerated if several violent expiratory efforts were made in succession. Eight months later the condition was still the same.

Deutsche medizinische Wochenschrift, January 5, 1905.

Bacteriological Observations in the Hot Water-Alcohol Method of Disinfection.—Sarwey discusses the technique by which Ahlfeld has endeavored to show that by his method of hot water-alcohol disinfection it is possible to render the hands sterile. Ahlfeld tests the hands for sterility by enclosing them for a certain length of time in a rubber globe filled with bouillon, and then incubating portions of this to detect possible bacterial growths, and he founds his claims on the results obtained in this way. The author repeated these experiments, but found that not one of the thirty-four different hands tested had been found sterile. Without exception it was demonstrated that the bacterial flora of the hands had been greatly reduced, but not wholly exterminated. The discrepancy is explained by the fact that Ahlfeld did not make a sufficient number of cultures from each hand, and that he used only bouillon as medium, whereas agar furnishes a much more suitable material for the growth of the hand bacteria The author, therefore, concludes that Ahlfeld's method does not possess the advantages claimed for it by its originator, and that it cannot bring about sterility of the hands.

The Treatment of Panaritium.—Riedel says that minor surgery has not kept pace with the advances of major surgery, and that because it usually has to do with infected tissues he dreads it more than he does major procedures. The infliction of apparently negligible slight lesions about the hand or fingers is usually disregarded by the laity and often by physicians also, yet the grave impairment of function, and even danger to life that follows neglected injuries of this sort renders them of the highest importance. The author treats such wounds of the skin as soon as noticed by leveling the surface of the epidermis around the lesion with a sharp knife and applying a piece of gauze coated with boric acid ointment, or vaseline. The flap of epidermis resulting from diagonal cuts should be trimmed down closely so as to expose the deepest part of the wound. If incision should be necessary in a case that has been allowed to go too long the finger or the wrist should be constricted with a rubber bandage and the part anesthetized by means of the old-fashioned ether spray. Ethyl chloride is too superficial in its action. Early incision is always advisable, for even though not so effective in causing the pain to abate as if performed later on, it nevertheless greatly shortens the course of the infection. Deep-seated inflammations with involvement of the tendon sheath require long incisions carried up the forearm and splitting the annular ligament at the wrist. The dissection in these cases is often a most difficult one, requiring the resources of an operating room, and for this reason such infections should not be treated by the general practitioner, but be at once referred to the nearest hospital. Secondary suture of the granulating incision is not advisable, but good cosmetic results are obtained by excising the scar after healing is complete and then suturing the skin edges, thus substituting a linear scar for the preceding broad one.

Antibacteriolytic Bodies in Normal Sera.—Pfeiffer and Friedberger describe experiments done to determine the presence of bodies antagonistic to bacteriolysis in normal serum. Cholera vibrios or typhoid bacilli were added to the normal serum in order to combine with the amboceptors, and were then removed by filtration or centrifugalization. When this prepared normal serum was added to a specific serum it was found that the bacteriolytic power of the latter was greatly inhibited. The normal serum of rabbits, goats and pigeons, but not that of the guinea pig, was so modified by temporary contact with these cholera or typhoid organisms that even when an excess of immune serum was added bacteriolysis of the corresponding organisms injected together with the serum into the guinea pig's peritoneal cavity did not take place. The bacteria multiplied freely and the animals died, whereas control animals were able to withstand the infection and got the better of the bacteria. It is possible to produce the effect not only *in vitro*, but also during during life. The serum of a rabbit that had received a heavy intravenous dose of cholera vibrios showed a marked inhibiting effect on cholera amboceptors a quarter of an hour after the injection. This inhibitory action is strictly specific, and serum treated with cholera vibrios is active only against typhoid amboceptors, and vice versa. The failure of bacteriolysis shortly before the close of a fatal infection may, in addition to the deficiency in amboceptors and complements, be to some extent due to the action of these antagonistic bodies.

French and Italian Journals.

Typhoid Bacilli in Relation to Vegetables.—Clauditz has made extensive researches to determine the external and internal infection of vegetables cultivated in soil infected with typhoid bacilli. He first made investigations under the direction of Rubner of Berlin, in order to determine the manner of growth of typhoid bacilli in earth. He found that the fresh bacilli adapt themselves with difficulty to new conditions. But he also discovered that when the typhoid bacilli are associated with native microorganisms of the soil, cultures can be obtained that are capable of living for months in the ground. Clauditz used these "adapted" typhoid bacilli for his experiments. With them he infected the soil in which he planted peas, radishes, cress, and other vegetables. When the plants had attained the height of from 5 to 8 cm., they were cut off level with the ground, and after being washed in sterilized water, they were bruised in bouillon. Out of four experiments, only one met with positive results—the development of a typhoid culture. Efforts were then made to discover whether the bacilli came from the surface or from the interior of the plants. The specimens were first washed in sublimate solution or dipped for ten or twenty seconds in hot water. The results were all negative. It would seem, then, that typhoid bacilli never penetrate to the interior of plants, even if the plants harbor these bacilli on their foliage or roots.—*Revue Française de Médecine et de Chirurgie,* December 19, 1904.

The Content of Glycogen in Each Lobe of the Liver in Relation to the Phases of Digestion.—Sérégé has performed certain experiments with dogs to determine the presence of glycogen in the liver. The dogs had first fasted for 48 hours. After the animals were fed, the writer found during gastric digestion a predominance of glycogen in the left lobe of the liver. During intestinal digestion, however, he found the greater quantity in the right lobe. But after the seventh hour and durng the fasting, even when prolonged, the larger amount was found in the left lobe. The functional independence of the two lobes is clearly shown for the right, but is less manifest for the left, on account of the last unexpected result. The investigator will seek to clear up this question by a study of the subhepatic blood vessels.—*Journal de Médecine de Bordeaux,* December 18, 1904.

Biological Theory of Sleep.—Claparède considers as erroneous the usually accepted conception according to which sleep is thought to be the consequence of an arrest of functioning, by intoxication and by asphyxia. He believes, on the contrary, that sleep is a positive function, an instinct which has for its purpose arrest of functioning. It is not because we are intoxicated or exhausted that we sleep, but we sleep in order to avoid these conditions. The fact that sleep is not proportional to exhaustion is an argument in favor of this theory. Sleep may be partial. One sleeps through certain noises, but not through others. Finally, the curve of the profoundness of sleep, inexplicable by the toxic theory, is in harmony with the theory that regards this phenomenon as a positive nervous function. The instinct, the reflex is provoked by numerous excitants: endogenous (condition of the blood, sensation of fatigue), exogenous (images empiratically associated with the idea of sleep). The phenomenon in itself is a reaction produced by these excitants and is an inhibition which manifests itself subjectively by a lack of interest in exterior things.—*La Presse Médicale,* December 21, 1904.

The Staphylococcus Pyogenes Aureus and Osteomyelitis.—J. Courmont and Ch. Lesieur report their experiments in which they infected rabbits by means of the yellow staphylococcus. These animals were attacked by acute osteomyelitis. The rabbits chosen for the experiments were 7 weeks old. The staphylococci which were injected into the blood were young and virulent cultures and were taken from furuncles. In these cases, pockets of purulent arthritis of the size of a nut were noted, subperiosteal spindles along the diaphyses, epiphyseal separations, osseus sequestra, little drops of pus in the bone marrow, and finally miliary abscesses in the renal pyramids. In all of these lesions the staphylococci existed in pure culture. The writers believe that, contrary to the assertions of Henke, the staphylococcus aureus, without the intervention of any other microbic agent, has a manifest tendency to localize itself in the neighborhood of epiphyses of bones in the process of growth, and can produce there lesions of suppuration and necrosis. The staphylococcus is always the microbe *par excellence* of the acute osteomyelitis of adolescents.—*Lyon Médical,* December 18, 1904.

The Influence of a Diet Poor in Chlorides on Metabolism.—Calabrese has studied the changes in oxidation in healthy persons on a diet of rich or poor in chlorides, and has found that as chloride of sodium is decreased there is a greater decomposition of albumins; he has studied the effect on the blood and found that it became poor in corpuscles and in hemoglobin. He concludes that chloride of sodium aids digestion not only as a condiment, but as an indispensable element for maintaining the normal condition of the organism. In some cases of hepatic cirrhosis he finds no fixed relation between the subtraction of chlorides and the presence of ascites. There is partial retention of the chlorides in this disease, but the amount of chlorides retained in the system is not the same as that execreted in the urine. He believes that the removal of chlorides from the diet is not beneficial in hepatic cirrhosis.—*Rivista Critica di Clinica Medica,* November 26, 1904.

Book Reviews.

Anatomie des Membres (Dissection, anatomic topographique). Par le docteur Ch. Dujarier, ancien prosecteur à l'Amphithéâtre de Clamart, chef de clinique chirurgicale à la Faculté. Avec 58 planches. Paris: G. Steinheil, 1905.

This work is a rather elaborate but practical guide to dissection; it tells the student both what to look for and where to look for it, and also gives instruction on the preparation of a finished dissection suitable for purposes of demonstration. The author having had several years' experience as prosector not only knows the requirements of students, but here more than supplies their needs. As will be seen from the title, this volume deals with the extremities only; but the work on this part is well done, and is illustrated with several colored plates, all prepared from the author's own dissections and eminently calculated to aid the student in his work in the dissection room. The whole book is of value; specially so are the chapters dealing with the axillary space, the bend of the elbow, the palm of the hand, the gluteal region, Scarpa's triangle, and the knee-joint; these, besides giving the ordinary anatomy, descriptive and topographical, go into considerable detail, so that those who use the book will not have to search elsewhere for further information.

Erste Aertzliche Hülfe, bei plötzlichen Erkrankungen und Unfällen. Von Prof. Georg Meyer. Second Edition. Berlin: Aug. Hirschwald, 1905.

It is quite true, as stated in the editor's preface, that instruction in First Aid to the Injured is usually directed to the laity, although it must be acknowledged that the physician himself is equally in need of information of this kind. The importance and care spent in the preparation of the work becomes evident when the list of authors is cited. The text is in the form of lectures addressed to the medical student and the practising physician, and those on surgical aids are contributed by von Bergmann; on internal diseases, by Carl Gerhard; on poisoning, by Oscar Liebreich; on obstetrics, by Martin; and on apparent death and unconsciousness, by the editor. This material is very exhaustively treated and yet arranged in such a manner that it may be used as a work of ready reference. It seems more suitable, however, for continued reading and the colloquial style adopted lends interest to the book. The popularity of the work may be gauged by the fact that the second edition has appeared within a year and a half after the first, and a translation in another language has also been published.

The Diseases of the Uterine Cervix. By H. I. Ostrom, M.D., New York. Surgeon to the Metropolitan Hospital, etc. Philadelphia: Boericke & Tafel, 1904.

The author claims that the diseases of the cervix and the body of the uterus must be considered separately, because there is not only an anatomical, but also a physiological distinction between these two parts. It has apparently been a difficult matter to limit the discussion to this topic, however, and the author also takes up pelvic surgery in general. The surgical treatment does not vary much in its general features from that which we meet in books written by others than homeopaths, but the tenets of the latter school are nevertheless in strong evidence in this work. There is also an appendix on therapeutics, in which indications for various remedies are tabulated. Some of the statements are interesting, if nothing else. The "allopathic mind" may be puzzled to know why "Kali bich." should be "suited to fair, light-haired persons, who suffer from catarrh," why the "tissue characteristic of Conium mac. is induration and hardness," why graphites are adapted to women who are inclined to obesity and why they affect the left ovary. The book is devoid of illustrations and it is tinctured too much with the principles of homeopathy to be of value to any one not a disciple of Hahnemann.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia, etc., assisted by H. R. M. Landis, M.D., Visiting Physician to the White Haven Sanatorium, etc. Volume IV. December, 1904. Philadelphia and New York: Lea Brothers & Company, 1904.

The present volume of this well-compiled conspectus of medical progress covers a wide range of subjects, which are interestingly annotated by the editors of the several departments. The principal sections are devoted to diseases of the digestive tract; anesthetics, surgery of the extremities and orthopedics; genitourinary disease; diseases of the kidneys; and a practical therapeutical referendum. Each of these is many times subdivided, and progress in the several departments is indicated by abstracts of the most important contributions which have appeared in native or foreign publications. The editors have shown much skill and discretion in welding these more or less disjointed fragments into a harmonious whole, which independently of its inherent interest makes agreeable reading, something of an anomaly in abstract literature. There is a liberal sprinkling of illustrations, including the inevitable brace of colored plates, which, as usual, are calculated to make the judicious grieve, but, no doubt, fulfill their purpose of enlivening the pages of a volume good enough not to require such brummagem embellishment.

Mechanical Vibration and Its Therapeutic Application. By M. L. H. Arnold Snow, M. D., Professor of Mechanical Vibration Therapy in the New York School of Physical Therapeutics; Associate Editor of the Journal of Advanced Therapeutics; Late Assistant in Electro-Therapeutics and Diseases of the Nervous System in the New York Post-graduate Medical School, etc.. New York: The Scientific Authors Publishing Co., 1904.

The growing popularity for physical methods in the treatment of disease here finds another work which describes the newer system of vibratory massage. The older, manual method, has gained a well deserved reputation but has the drawback of being too exhausting for the average therapeutist and if the perfection of mechanical means will make up for the lack of delicacy which the sense of touch affords we shall have a valuable addition to our system of treatment. The author herein describes the history and development of mechanical vibration, the different vibrating machines whether operated by hand, by compressed air, or by electricity, and the principles which underlie their different actions. The general physiological action is then considered in so far as we at present understand it. One chapter is given to the effects on the circulatory system, another to the nervous system, and another to the muscular system. The author also considers some of the general laws which are applicable to the methods in use, describing the points of application, the advantages of rapid and slow vibration, the amount of pressure to be used, and other points in technique such as would be valuable to those contemplating further investigation of the subject.

Quite a number of plates descriptive of the various instruments which are on the market with their different actions adds to the value of the work and will enable the reader to select such as would be best adapted to his special line of work.

A Laboratory Manual of Human Anatomy. By Lewellys F. Barker, M.B., Professor and Head of the Department of Anatomy in the University of Chicago and Rush Medical College. Assisted by Dean De Witt Lewis, A.B., M.D., and Daniel Graisberry Revell, A.B., M.B., Instructor in Anatomy in the University of Chicago. Illustrated. Philadelphia and London: J. B. Lippincott Company, 1904.

Here is a new laboratory manual of anatomy designed to take the place of what have been known in the past as dissection guides. From many of these it differs very considerably both in the quality and the quantity of the work which it exacts; to most of them it is superior, to the best of them it is equal. Students seeking short and easy methods will do well to avoid this book; but the earnest student will welcome it as a most serviceable guide in the dissecting room, and at the same time he will appreciate the conscientious and painstaking habits of study which will be inculcated by its use. The volume commences with an introduction containing sections on the instruments needed in dissecting, their care and use; preservation of the part; drawing; books, including textbooks, reference books, and atlases; and on anatomical terms. This is followed by the main body of the book, in which each portion of the cadaver is considered in turn, and the student is taken thoroughly and carefully over the upper extremity, lower extremity, head and neck, dorsum of trunk, thorax (walls and viscera), abdomen, and pelvis. Among the many points of excellence may be mentioned the repeated insistence on drawing the parts dissected; the constant reference to standard textbooks and large atlases; the entire absence of information to be found in the textbooks, such as descriptions, origin and insertion of muscles, etc.; the double system of nomenclature, viz., the scientific one formulated by the German Society of Anatomists, and the old one still used in the majority of books. The illustrations number nearly three hundred, and satisfactorily represent the most important structures of the body. There can be no doubt that the use of this book will do much to advance the practical study of anatomy; it will lighten the labors of the instructor and render the student such guidance as he requires.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Thirty-second Annual Meeting, Held at Havana, Cuba, January 9, 10, 11, 12 and 13, 1905.

The Association met at the Athenaeum Club, under the Presidency of Dr. Carlos J. Finlay of Havana.

Following the transaction of routine business, such as the election of over a hundred new members, etc., the reading of papers was begun.

Purification of the St. Louis Water Supply by Using Ferrous Sulphate and Calcium Hydroxide as a Coagulant, Followed by Plain Sedimentation.—This paper was read by Dr. C. A. Snodgrass of St. Louis, and was of particular interest, for the reason that, according to the claims of the author, it set forth a simple, practical, and inexpensive method of handling large quantities of surface water. It called attention to the fact that from the year 1832, the time at which the first water works system of St. Louis was installed, until 1904, the water supply of St. Louis had been unsatisfactory, and that in a few months' time a complete transformation of the quality of the water had been secured. The comparative cost with other proposed methods was most striking. One of the proposed methods called for an original outlay of $31,000,000; another $2,700,000, while the present plant required only $10,000 for its construction. This plan of operation was shown to cost $4.50 less per million gallons than any other proposed plan. The exact and extensive chemical and bacteriological data added to the physical properties proved conclusively that a water of a high degree of potability was being secured. The removal of suspended matter was shown to average 96.9 per cent., whilst the bacteria removed averaged 95 per cent. in many weekly analyses, showing an efficiency of 99 per cent. Mineral analysis showed that there was nothing left in the water that could be inimical to health. The death rate from typhoid fever during the last year had been materially lowered, but owing to the limited time of operation of the present system, no deductions from this point of view were insisted on. Reports from engineers and manufacturers showed that the treatment given the St. Louis water supply was highly satisfactory to their interests. It was the opinion of the writer that little or nothing would be gained by adding mechanical filtration to this system. Attention was called to the difficulties which were unavoidable in the institution of this plan into the previously existing plant, and it was claimed that with contemplated changes of a minor character the expense of operation would be lowered and the efficiency increased.

Copper Sulphate Method for Removal of Germs From Water.—Mr. F. S. Hollis of New Haven, Conn., contributed a paper in which he described a practical test of the copper sulphate method for the removal of germs from water supplies.

Report on Purification and Preservation of Water Supplies.—Mr. Geo. W. Fuller of New York presented the report of the Committee on Purification and Preservation of water supplies. He stated that the principle of the use of sulphate of copper in treating water supplies was not a new one, as it had been used for thousands of years. With reference to filtration, he said the number of cities in the United States, with a population of 25,000, now using the filtration plan, was about 8 per cent., those which had filters under construction, 11 per cent., those in which filters had been authorized, 20 per cent., and those in which filters were being considered necessary, 31 per cent. Statistics and arguments were advanced in favor of filtration as a method of purifying water supplies of cities.

Dr. Frank Warner of Columbus, Ohio, stated that in considering the improvement of any public water supply, more attention should be given to the better protection of the watershed. This feature was either neglected or overlooked in connection with modern purification plants. This was especially true of pollution near the purification works, and the water should be delivered to the purification plant in as pure a condition as possible.

Mr. H. W. Clark of Boston said that since the introduction of filtration at Lawrence, Mass., the city had increased in population from 45,000 to 75,000, and the percentage of deaths from typhoid fever had been materially reduced.

Mr. Robert S. Weston of Boston stated that other questions of purification of water must be settled before any one method could be universally used.

Disinfection and Desinfectants.—At the afternoon session the report of the Committee on Disinfection and Disinfectants was read by Professor F. C. Robinson of Brunswick, Maine. The report was a review of the more important literature on the subject during the past year, especially in the foreign journals. As to experiments on disinfecting railway cars by formaldehyde, the results showed that in case of passenger cars it was practically impossible to sterilize completely all parts by the vapor of formalin, but still the experimenters think that it is the most practical thing to employ for that purpose. They recommend 1,000 c.c. of the liquid formalin to each car, but of course the cars are much smaller than those in use in the United States. As to chemical methods for sterilizing drinking water, V. B. Nesfield recommends the use of tablets made from 1½ grains bleaching powder and ½ grain sodium bicarbonate. He claims that these will each sterilize a pint of water in five minutes, or better, ten. He removes the paste of chlorin by adding a tablet of sodium sulphite. He claims that by such use the most foul river water can be made free from disease germs and palatable.

With regard to the disinfection of books, the report called attention to the danger of the spread of infectious diseases through library and school books. It was recommended that the danger should be met as far as possible by notices in libraries calling attention to the advisability of handling books with clean hands, of not putting the hands to the mouth after touching books until the hands are washed, and in addition submitting books much used to the action of formaldehyde vapor once in a while. Remarkable results had followed the occasional use of weak solutions of formaldehyde on the floors of school houses—solutions so weak that they gave no disagreeable odor. Infectious colds and other dust-borne diseases were much lessened among the scholars. The committee believes that the occasional use of such solutions on floors and surfaces in dwelling houses as well as public buildings would do a great deal towards improving public health.

The Use of Sulphate of Copper Alone or in Combination With Lime for the Destruction of Mosquito Larvæ as a Deodorant and as a Disinfectant.—Dr. A. H. Doty of New York contributed a paper with this title. (See page 90.)

The Disinfection of School Books.—Dr. Walter D. Greene of Buffalo, N. Y., stated that the examination of the public school books early in 1902 revealed the fact that they were filthy, especially those used by the lower grades. These books were furnished gratuitously by the city, and consequently there existed a tendency to use them until they were literally in pieces—a period covering several years. It was thought that these filthy books, worn and handled by so many diminutive individuals, might be, and probably were, a source of contagion, and it was decided to disinfect them. The books were placed on their edges with covers widely separated upon tables and shelves in tightly sealed rooms. Formaldehyde gas was liberated in the room, six ounces of a comparatively fresh commercial formalin being used for every one thousand cubic feet of air space, the vaporization being induced by the use of wood alcohol burned in a receptacle containing the formalin. Bacteriological examinations were made of the soiled leaves of books both before and

after disinfection, and it was found that about 85 per cent. of all organisms were killed. For the three years immediately preceding this schoolbook disinfection—that is, 1899, 1900, and 1901—the average number of cases of scarlet fever reported to the health department by physicians in Buffalo was 875 yearly, while the average yearly deaths for the same time was 36. For the three years following such disinfection, the average number of cases reported yearly was 528, and the number of deaths yearly for the same time was 18. He hoped the results of these investigations would stimulate health boards and health officers to disinfect the schoolbooks of their respective municipalities.

The Sources of Infection.—Dr. Charles V. Chapin of Providence, R. I., after pointing out various sources of infection, directed attention to isolation and disinfection. He said that it was perfectly plain, if we could isolate every case of a given contagious disease until all infection had disappeared, the disease would not merely decrease, but it would be exterminated. If we could control only one-half, one-quarter, or one-tenth of the foci of infection, it was equally clear that the disease would never be exterminated, and it was not even certain that it would diminish. The relation of probable success to the efforts made must decide the extent of those efforts. It was the writer's opinion that for most of the diseases, and for most localities, restrictive measures were either carried too far or were not carried far enough.

The Actual Sanitary Conditions of Havana and the Further Requirements for Their Improvement.—Dr. Erastus Wilson of Havana said that the prevailing annual mortality in the city of Havana previous to American intervention—1898-1902—approximated 40 per thousand. The general cleaning up of public places and rigid house-to-house inspection and abatement of unsanitary domestic conditions, together with filling the puddle holes and irregularities in the macadamized streets, with the prohibiting of the ejection of domestic wastes into the by-ways, obtained immediate and notable reduction in the mortality rate in the city. The continuation of the sanitary measures introduced by that intervention and the continued improvements of the pavements of streets had reduced the mortality and morbidity to about 50 per cent. of their former rate, besides beautifying the city and making it infinitely more attractive for residents who were interested in health and general culture.

The author called attention to a further requirement of sanitary science, which was radical and indispensable, namely, a modern system of sewers of proper section, regularly graduated in size and declivity from their incipience to outfall, impermeable throughout and connected with the closets of every house by lead-jointed, cast-iron pipes, uniting them to the sewer outside the domicile.

Following Dr. Wilson's paper, a resolution was offered and adopted: "That the Association congratulates the civic authorities, the physicians, and the people of Havana in general upon the gratifying improvement made in its sanitary condition, and especially upon their work in freeing their beautiful city from any danger from that once dreaded scourge—yellow fever—by their persistent and skilful campaign against the yellow fever mosquito. We are especially gratified also that they do not propose to rest contented with what has been done, great as it is, but have already planned other sanitary improvements of great importance, including an efficient system of sewerage, which we wish them Godspeed in carrying out at the earliest practicable moment."

Addresses of welcome were delivered by Dr. Cancio, Secretary of Public Instruction to President Palma, representing the Cuban government, and by Dr. Lincoln de Zayas, representing the medical profession of Havana.

President's Address.—The President, Dr. Carlos J. Finlay, after thanking the Association for the great honor that had been conferred upon him in electing him President, referred to the first Havana yellow fever commission, which was established a quarter of a century ago, and came from Washington to prepare the ground upon which a common enemy would be subsequently challenged and decisive battle fought. This enemy was the yellow fever. So well did this commission accomplish its object, that he could readily trace back to its immediate influence the discoveries which led the way to ultimate success. After referring to the deaths of several prominent members that had occurred during the year, he stated that the sanitary experience in Cuba during the last twelve months, with regard both to yellow fever and to smallpox, had been somewhat more eventful and at the same time more instructive than in the preceding two years. In the district of Havana, notwithstanding the admission of imported cases of yellow fever from foreign ports, not a single case, originating on the island, had been recorded.

The fight against tuberculosis must be maintained at all costs, as that was the most important factor in mortuary statistics of large towns, almost all over the world. The study of causes and prevention of infant mortality was one which affected Cuba not only with reference to infantile enteritis, but with regard to tetanus neonatorum, the occurrence of which was coupled with unpardonable ignorance or neglect on the part both of parents and of the attendants at the birth of children. The control of milk supplies in large cities was closely connected with infantile mortality, for the methods best calculated to carry the former into effect should undoubtedly lessen the latter. Finally, the subject of sanitary agreement between adjoining nations had become of paramount importance since the recent advance made in our knowledge of the etiology of certain quarantinable diseases, of yellow fever in particular. Hence the advisability, that European nations holding possessions in the American yellow fever zone, be represented at the meetings of the Association.

Dr. Benjamin Lee of Philadelphia read a tribute to Dr. Carlos J. Finlay for his distinguished services to science and humanity in the discovery of the mode of propagation of yellow fever.

Bacillus Tuberculosis in Man and Animals.—In the absence of Dr. M. P. Ravenel, Chairman of this Comtee, the report was read by Dr. V. C. Moore. Since the last meeting, several important pieces of work had been reported. These were detailed in the report. The Committee carefully compared the disease set up in the bovine animal by material of bovine origin, and so far it had found the one, both in its broad general features and in its wider historical details, to be identical with the other. It had so far failed to discover any character by which it could distinguish one from the other; and its records contained accounts of the post-mortem examinations of bovine animals infected with tuberculous material of human origin which might be used as typical descriptions of ordinary bovine tuberculosis. At the laboratory of the State Live Stock Sanitary Board of Pennsylvania, a third instance of infection with the bovine bacillus had been found. The case was that of a child not quite two years old, who had been nourished the greater part of its short life on cow's milk, bought from the most convenient store. It developed a large abdominal tumor, which proved on autopsy to be a tuberculous new growth, involving the mesenteric glands and intestines. The lungs were not involved. Cultures were obtained from this tumor, which had the cultural and miscroscopic characteristics of the bovine bacillus, and proved fatal to a calf weighing 211 pounds, in thirty-five days. The Committee did not yet feel able to say with what frequency bovine infection of man took place, but it was evidently not a rare occurrence. The Committee considered that the evidence going to show that such infection did take place was absolutely conclusive, and that it not only justified, but made imperative, the passage of stringent laws by municipal and

State authorities for the suppression of tuberculosis in cattle, and the prohibition of the sale of meat and milk from tuberculous animals.

Dr. Jesús E. Monjaras of Mexico City contributed a paper entitled, "Measures Proposed in the Struggle Against Tuberculosis."

Report of the Committee on Tuberculosis.—In the absence of the Chairman of the Committee, Dr. Lawrence F. Flick of Philadelphia the secretary read this report: The practical measures recommended years ago had since been tested in part, and so far as tested had been found of use. These recommendations were: "(1) The notification to and registration by health authorities of all cases of tuberculosis which have arrived at the infectious stage. (2) The thorough disinfection of all houses in which tuberculosis has occurred, and the recording of such action in an open record. (3) The establishment of special hospitals for the treatment of tuberculosis. (4) The organization of societies for the prevention of tuberculosis. (5) Government inspection of dairies and slaughter houses and the extermination of tuberculosis among dairy cattle. (6) Appropriate legislation against spitting into places where the sputum is likely to infect others and against the sale or donation of objects which have been in use by consumptives unless they have been thoroughly disinfected. (7) Compulsory disinfection of hotel rooms, sleeping car berths, and steamer cabins, which have been occupied by consumptives before other persons are allowed to occupy them." In addition to the specific recommendations here given, the committee urged upon the public the importance of better housing of the poor in their places of abode and in their places of occupation; better control of the food supply at large, and more definite instructions in the schools and on the platform regarding diet for the working people. The home and workshop were really the centers from which the disease was distributed, and they at the same time were strong predisposing causes of the disease by reason of their unhealthfulness. Bad and adulterated food and improper selection of food by the individual were also strong predisposing causes by lowering vitality. The committee suggested that every member act as a committee of one in his own home to help organize a campaign against this disease.

Dr. Walter D. Greene of Buffalo, N. Y., said that tuberculosis was a subject of vital interest, inasmuch as one-tenth of all deaths occurred from this disease. There were two things of special interest in combating the disease, one of which was notification of cases, and the other thorough disinfection of houses in which the disease had occurred. In the city of Buffalo every house in which a case of tuberculosis had developed was thoroughly disinfected. This had been the practice in that city for the last five years. A card index was of vital importance in keeping track of cases of the disease. The people should be educated in regard to the prevention and control of the disease. Pamphlets giving directions how to keep from getting the disease were printed in Buffalo in the German, English, Polish, and Italian languages. Directions were also given as to what to do when people contracted the disease.

Dr. Frank Warner of Columbus, Ohio, said the reporting of cases of tuberculosis was an important factor in the prevention of the disease, but it was only the first step. This should be followed with literature placed in the hands of families in which the disease had developed. Information regarding the disease should also be published and put into the hands of men working in stores and shops. Articles relating to the disease should be published in the daily newspapers for the edification of the public. He pointed out the importance of educating the people through the press and other agencies. The disinfection of houses after deaths had occurred was of great importance in order to destroy the germs of the disease. Testing for tuberculosis in cattle by tuberculin had proven a very important thing. At the Ohio State University there was an agricultural and dairy department, so that every cow was constantly tested with tuberculin for tuberculosis, and whenever the disease was found in a cow, that animal was withdrawn from the herd.

Dr. R. H. Lewis of Raleigh, N. C., endorsed the position taken by the previous speaker. In his State pamphlets concerning the disease and its prevention were placed in the hands of the superintendents of public instruction and of school teachers for distribution. The active cooperation of the family doctor should be enlisted.

Dr. Marcus Haas of Memphis, Tenn., agreed with the speakers in regard to educating the public as to the prevention and control of the disease. Negroes in the South were more susceptible to the disease than whites. He referred to the thorough system of dairy and milk inspection in Memphis, saying that gratifying results had been obtained by it.

Dr. W. C. Chapman of Toledo, Ohio, said that sanitarians should not demand too much of the physician, for in doing so they would undo the benefit which they might otherwise receive. Physicians were reluctant in reporting cases of tuberculosis to city health departments, on account of the protests of families in which the disease had developed.

Dr. Manuel S. Iglesia of Vera Cruz, Mexico, described the present hygienic conditions of that city, and expressed the hope that at no distant day this port would be one of the healthiest to be found.

Dr. Arístides Agramonte of Havana pointed out the practical utility of a medical board to aid local sanitary authorities in the investigation of infectious disease.

Diphtheria Infection in Minnesota, Especially in School Children, and Institutional Epidemics.—Dr. F. F. Wesbrook of Minneapolis stated that in the work of the Minnesota State Board of Health the problems had naturally arranged themselves into three main groups: First, the work of dealing with diphtheria as it occurred in family life, where one or more cases appeared in a household. Second, when infection was widespread and the day schools had to be closed. Third, when infection gained entrance into institutions in which children or other inmates were housed, employed, taught, or confined, and where great opportunity for the spread of infection was present. In summing up the work, he said it was apparent (1) that an adequate laboratory staff and equipment were essential since only by thorough laboratory examination could the presence of possible danger be determined. (2) It had been found convenient to utilize institutional laboratories when available, as the members of the laboratory staff of the State Board of Health could examine cultures on the spot when there was urgent need of haste. (3) The repetition of examination of both nose and throat specimens was advisable in all cases, and especially when suspicious bacilli were found. (4) Every effort should be made to prevent the exchange of nose and throat bacteria between individuals until it was definitely known whether they were infected or not. In infected individuals the bacilli would be eliminated more quickly the greater the approximation to individual isolation. (5) It was unsafe to place hitherto uninfected individuals who developed sore throat with clinical cases of diphtheria. (6) Executive action must be taken on the basis afforded by the laboratory; therefore, it was essential that these two branches be kept in the closest touch, or that in the work of inauguration and supervision of methods a laboratory trained man be placed in charge. (7) That such methods give satisfactory results and were entirely practicable, had been shown in the experience of the Minnesota State Board of Health under conditions which presented the greatest possible variation. Three epidemics had thus been suppressed in a lying-in hospital in Minneapolis where there was no adequate nursing force, where the women before and after confinement were employed in the

housework of the institution, where the babies were left in charge of different mothers at different times, and where also the almost daily admission of fresh inmates added to the opportunities for the introduction of infection. (8) The experience of Minnesota would seem to point decidedly to the conclusion that diphtheria infection is transmitted usually by almost direct exchange of flora of the nose and throat.

Dr. Samuel H. Durgin of Boston followed with the report of the committee on the infectious period of communicable diseases.

Social Hygiene.—Dr. Adolpho Oliva of Guadalajara, Mexico, read a paper on this subject, in which he pointed out the effects of dress on the system. He also discussed the various forms of dress. He said that variations in temperature of the system with the climate, seasons, age, constitution, and the conditions of health or of disease fully demonstrated the physiological necessity of dress.

Yellow Fever in Mexico.—Dr. E. Licéaga of Mexico read a paper on this subject, in which, with the aid of numerous charts and diagrams, he described how houses that were infected with the disease were disinfected. As soon as a case of yellow fever was found, the patient was isolated, the mosquitos and larvæ were destroyed. The Vera Cruz campaign against yellow fever had been very successful, in that there had not been any epidemic of the disease in that city for the last six months. He cited one case to prove, without doubt, that yellow fever was transmitted by mosquitos alone.

Control of the Milk Supply in Large Cities.—Dr. Wm. H. Park of New York City read a report on this subject. The topic was divided under three heads: (1) The proper conditions at the farms, (2) proper conditions during transportation of the milk, and (3) proper conditions at the delivery station and in the case of the milk in the homes. Until recently the conditions at the farms had been largely overlooked by the health officers of great cities, on account of the practical difficulties and the expense. The Milk Commission appointed by the Medical Society of the County of New York had undertaken to assist both the consumer and producer by fixing a standard of cleanliness and quality to which it could certify, and by giving information concerning measures needful for obtaining that degree of purity. The most practical standard for the estimation of cleanliness in the handling and care of milk was its relative freedom from germs or bacteria. Milk must not be sold as certified more than twenty-four hours after its arrival in New York City. The report discussed the duties and requirements of dealers in milk, the barnyard, the stable, the condition of the cows, the milkers, helpers other than milkers, small animals, the milk itself, the utensils for holding milk, as well as the examination of the milk and dairy inspection.

Dr. Gonzalo Aróstegui of Havana discussed the importance of good quality and careful distribution of the milk supply.

Infantile Feeding by Nurses.—Dr. Alfonso Pruneda of Mexico read a paper on this subject, and said it was necessary always to advocate the need of maternal lactation, which was really adequate from every point of view, but in the event of this being found impossible, we should not hesitate to adopt some other methods and especially should we avoid the employment of wet nurses against whom, as the writer pointed out, there were many objections, but rather make use of sterilized milk, which, when properly and methodically used, would fulfil its purpose, and thus save the lives of many children who would under other conditions perish.

Production of Animal Vaccine.—Dr. W. F. Elgin of Glenolden, Pa., followed with a paper in which he described experiments and his experience in the production of animal vaccine. The author pointed out (1) that virus exposed to cold below 0° C., might remain active for an indefinite period, certainly for several years. (2) That when it was removed from cold storage, it would retain its activity for a considerable period under conditions that usually obtained commercially. (3) That when glycerinated lymph was exposed to 0° C. or below, the destruction of germ life through the action of the glycerin was practically at a standstill. (4) The rapidity of the elimination of the contained bacteria depended upon the temperature above 10° C., in which the virus was stored. The writer showed that the life of the average commercial vaccine was only three months in winter, and in August and September only about one month. Two lessons might be learned from this: (1) one should not vaccinate in the summer season unless compelled to do so by the presence of smallpox; (2) when compelled to vaccinate at this season, one should order the vaccine direct from the laboratory and use it at once.

Dr. F. P. Bernaldez of Mexico cited facts and arguments which tended to demonstrate the superiority of humanized over animal vaccine for the prevention of smallpox. He claimed that persons who were vaccinated and revaccinated with humanized lymph enjoyed a longer immunity, according to his observations, and in Mexico he had never seen a person so vaccinated attacked by smallpox. His practice had taught him that in such persons revaccination did not take, or at most assumed the appearance of false vaccination, thus proving in his opinion that the individual was not susceptible. He urged that vaccination be practised by physicians of experience in order to avoid the possibility of transmission of disease.

Dr. Vicente de la Guardia of Havana spoke of the necessity of vaccination and revaccination of individuals who had suffered from smallpox. He said that in most countries nowadays there was no vaccination requirement for individuals who had had smallpox. He had had the opportunity of vaccinating and revaccinating 1,599 persons, members of the police department, custom house inspectors, port policemen, persons confined in jails, males and females, etc. Of this number, 328 were branded with the smallpox trademark, 47 of whom were vaccinated for the first time in their lives, and in these 17 vaccinations were successful. Two hundred and sixty-three were revaccinated, in 48 of whom it took successfully, giving a total of 665 successful vaccinations. The author concluded by insisting that, as a general rule, all individuals, whether they be ex-victims of smallpox or not, should be vaccinated or revaccinated, as the case might be.

Stegomyia Fasciata.—Dr. Fernando Lopez of Mexico detailed some experimental studies on the acclimatization of this insect. The experiments seemed to prove that *Stegomyia fasciata* could live, bite, and breed for at least three generations in Mexico City, notwithstanding the fact that this city had an altitude of more than 7,300 feet above sea level.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. F. F. Wesbrook, Minneapolis, Minn.; *First Vice-President,* Dr. Juan Guiteras, Havana, Cuba; *Second Vice-President,* Dr. F. Lopez, Mexico City, Mexico; *Third Vice-President,* Dr. Geo. MacDonald, Brandon, Manitoba; *Executive Council,* Drs. Marcus Haas, Memphis, Tenn., C. V. Chapin, Providence, R. I., and Wm. C. Chapman, Toledo, Ohio; *Secretary,* Dr. Chas. O. Probst, Columbus, Ohio, re-elected; *Treasurer,* Dr. Frank W. Wright, New Haven, Conn., re-elected.

After the introduction and adoption of resolutions of thanks to the local Committee of Arrangements, the President of the Republic of Cuba, and the Minister of the United States, for the receptions so graciously given in honor of the members, the Association, on motion, adjourned to meet next year in Boston, Mass.

LABORATORY SECTION.

The meeting of this Section was held at the General Wood Laboratory, January 9, 1905, under the Chairmanship of Dr. V. A. Moore of Ithaca, N. Y.

The session was devoted very largely to water and sew-

age. Mr. George W. Fuller of New York, Chairman of the Committee on "Standard Methods of Water Analysis," submitted an exhaustive report on the changes and improvements in the methods that are being used in bacteriological tests of water. The report was ordered to be tributed to bacteriologists, both in this country and in Europe.

Reports of committees on a variety of technical subjects and several papers on bacteriological topics were read.

The Persistence of Agglutinability in Typhoid Bacilli in Water.—Prof. Edwin O. Jordan of Chicago contributed a paper on this subject. Both the theoretical and practical problems involved in either a positive or a negative result from experiments upon the agglutinability of typhoid bacilli in water were of considerable interest and importance. This work had dealt chiefly with two aspects, that of the separation of bacillus typhosus and bacillus coli from mixtures of various ages in both tap water and previously sterilized sewage, and also the persistence of the agglutinability of the former after association with the latter for similar periods. The conclusions drawn were (1) that the typhoid bacillus may be isolated without special difficulty after association with bacillus coli in tap water and sewage for from at least twelve to twenty days; (2) that some strains of bacillus typhosus retain their property of agglutinability absolutely intact under these conditions.

A Cause of the Formation of Gas in Cans of Condensed Milk.—Mr. Chas. W. Dodge of Rochester, N. Y., stated that bacteriological investigations of the condensed milk in cans, which were found to bulge shortly after their preparation, failed to find any microorganisms which, either singly or in combination, would cause the fermentation of either dextrose or lactose under a variety of conditions usually favorable to such fermentations. Neither would the milk itself from such cans cause fermentation in fresh milk. It was found, however, that when dilute solutions of butyric or lactic acid, varying from 1:200 to 1:500 in distilled water, were allowed to act upon the metal of which the cans were made, a slow evolution of gas took place, its rapidity being inversely as the dilution of the acid. It was probable that in the instance cited the gas was formed not by the bacteria directly, but the electrolytic action between the metal of which the cans were composed and the acids generated by the growth of bacteria in the milk before the latter was condensed.

An Unusual Channel of Infection With the Bacillus Shiga.—Mr. Dodge stated that a laboratory worker accidentally broke a test tube containing a culture of the Shiga bacillus, and some of the fluid was carried to his eye, and was probably washed down into the pharynx. Twenty-four hours later typical clinical symptoms of acute dysentery appeared, and lasted for several days. This occurrence of the accident and the infection might be merely a coincidence, but, if not, the occurrence threw light on the rapidity of infection in dysentery in man.

An Improvement in the Technic of the Indol Test.—Drs. Joseph McFarland and J. Hamilton Small of Philadelphia contributed a joint paper on this subject. In order to render it possible to determine the presence of small quantities of indol in bouillon cultures, the following improved technic was devised: The culture to be tested received an addition of one drop of chemically pure sulphuric acid for each cubic centimeter of fluid, this being well shaken. In case the microorganisms produced both indol and nitrites, the red color now made its appearance. When, however, the organisms produced no nitrites, the usual dilute solution of potassium nitrite was allowed to trickle slowly down the side of the tube and form a layer on the surface of the fluid it already contained. The red color of the nitroso-indol now made its appearance at the line of contact of the two fluids. Tests on artificially prepared solutions of indol of upwards of 1:750,000 gave positive results. The authors stated that this improved method was applicable for showing the presence of indol in melted gelatin cultures. After the gelatin had hardened, the color ring was fixed for a period of from twelve to twenty-four hours, when the color became diffused.

Mr. Freeland Howe, Jr., detailed some results in the use of different kinds of nutrient media with different periods of incubation, and gave the results of observations on the water of the Susquehanna River at Harrisburg, Pa.

Dr. F. C. Harrison of Guelph, Ont., gave the results of an examination of the water supply of Fredericton, N. B. He discussed briefly the sewerage and water supply systems of that city.

Mr. Earl B. Phelps of Boston contributed some notes on the determination of the organic nitrogen in sewage by the Kjeldahl process.

Officers.—The election of officers resulted as follows: *Chairman,* Dr. Wm. H. Park, New York; *Vice-Chairman,* Mr. H. W. Clark, Boston; *Secretary,* Dr. John S. Fulton, Baltimore; *Recorder,* Dr. H. D. Pease, Albany.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held January 19, 1905.

Dr. Charles A. Dana, President, in the Chair.

Presentation of a Portrait of the Late Geheimrath Peter Dettweiler on the Anniversary of His Death.—Dr. S. A. Knopf made this presentation. (See page 136.)

Note on Wood Alcohol Neuritis.—Dr. Smith Ely Jelliffe read this paper. He said that in view of the recent bringing to light of the fact that many deaths had been caused by the use of methyl alcohol used as an adulterant to strong liquors, and by reason of the renewed interest taken in the subject of methyl alcohol optic neuritis, it seemed pertinent to inquire if types of neuritis other than that affecting the optic nerve might be caused by the use of methyl alcohol taken internally either as a liquid or as a vapor. His communication was limited to some personal observations on peripheral neuritis resulting from the use of wood alcohol. Of this affection three patients had come under his observation. The first was a business man, 34 years old and a constant drinker, particularly at night before going to bed He drank a special brand of whiskey which, on analysis, was found to contain 35 per cent. columbian spirits whiskey with suitable flavors to make a "richly blended article." The patient had been indulging in this and other brands of whiskey for at least three months, if not six. He began to suffer from severe gastric irritability and marked hyperesthesia in the upper extremities, particularly in both arms and hands. This was followed by complete paralysis of the extensors and typical wrist drop. He also had a mild grade of ptosis. He was partially amblyopic. The patient recovered after four months of treatment, but still complained of some blurring of vision. Dr. Jelliffe was able to exclude practically all other causes for the neuritis, which did not differ in any particular from neuritis due to ethyl alcohol. The two other cases showed a much lighter grade of the affection, and a different mode of ingress of the poison. Both patients were painters, particularly varnishers, doing nothing but shellac work on furniture, working long hours and in comparatively small rooms. The shellacs used were dissolved in wood alcohol, and the patients were exposed to the evaporating fumes. Both suffered from the hyperesthetic forms of the disease, the upper extremities alone being involved. There were the familiar paresthesia, numbing, pricking, and shooting pains in the backs of the hands and forearms. The pains were at times severe, and there was intense pain on pressure over the nerve trunks. The joints were involved to a slight extent. There was a marked degree of edema or puffiness. There was distinct motor weakness in both patients. These were instances, Dr. Jelliffe believed, of beginning peripheral neuritis due to the fumes of wood alcohol. He then reviewed briefly what we as yet know regarding the comparative toxicity of the different alcohols, particularly the peculiar characteristics of wood alcohol.

Dr. Alexander Lambert said that the adulteration of

whiskey by wood alcohol was of recent date. His experience in the alcoholic cells dated back ten years; during that time there had been as many as 50,000 to 60,000 cases of which he had personally observed 15,000. He never remembered seeing a single case of poisoning that he was willing to state was due to wood alcohol. He had never seen a single case of blindness coming on. During recent years he had been struck by the differences in effects upon individuals when they had ingested good and bad cheap whiskeys. He thought for a long time that the bad effects were due largely to the fusel oil, but he found that he was mistaken. Those individuals who took what appeared to be an ordinary drink of whiskey, made up largely of methyl alcohol, would come in thoroughly drunk, and many hours would be spent in attempts to keep them from dying. Then again there would appear another kind of drunk with delirium, and who would fight furiously, far beyond what an ordinary subject of alcoholic poisoning would do. It would last a long time and come on very rapidly. Dr. Lambert believed that the tendency to dilute these cheap whiskeys with methyl alcohol had much to do with it.

The Fresh Air Treatment of Surgical Tuberculosis.—Dr. Linsley R. Williams read this paper. He said he would confine his remarks to a consideration of the fresh air treatment of surgical tuberculosis in children, and called especial attention to the work that was being done by the New York Association for Improving the Condition of the Poor at Coney Island. In these cases it had been recognized that country air was needed, and that sea air was the better. There were a very few hospitals in this city that had country homes to which to send these cases of surgical tuberculosis. He said that in the summer of 1903 Mr John Seely Ward, Jr., of the Board of Managers, during a visit to Europe, undertook, at the request of the Board, to inspect various French hospitals for the treatment of tuberculosis. Upon his return he reported that while in the treatment of children suffering from tuberculosis of the lungs, American methods were quite as advanced as those in France, the same could not be said of our treatment of children suffering from non-pulmonary forms of tuberculosis. This seemed all the more remarkable if it was remembered that when tuberculosis attacked children it was more frequently in the bones or lymph glands or skin or abdominal organs, etc., rarely in the lungs. The American treatment of these cases differed from that of French seaside hospitals, in that here we attempted to arrest the tuberculous process by operations, braces, and indoor treatment. The French seaside sanatoria, on the other hand, treated by salt air, ample nourishment, and outdoor life. French experts maintained that for this treatment there should be one bed at the seashore for every thousand population. America had none. New York should have at least 3,500. The Board of Managers was strongly urged to undertake to demonstrate for American hospitals, and more particularly for American city and state governments, the healing powers of outdoor treatment in the salt air for non-pulmonary forms of tuberculosis in children. On June 6, 1904, with the cooperation of the Medical Advisory Board, composed of Drs. Walter B. James, Herman M. Biggs, John Winters Brannan, Lawrence F. Flick, V. P. Gibney, E. G. Janeway, Newton M. Shaffer, and E. L. Trudeau, for hospitals, settlements, and dispensaries, they had conducted on rented land only one hundred yards from Sea Breeze, an experimental Seaside Tent Camp for the Salt Air Treatment of Children suffering from Tuberculosis of the Bones and Glands. The character of the plant and the advantages of the ocean and beach were indicated by photographs and stereopticon views. During the summer the tents were always open. The children took daily baths in the ocean when the weather permitted. The children were kept outdoors except at meal time. A teacher had been employed who gave them instruction for two hours five days a week in a bright and airy room. In winter the children were warmly clad. Much stress was laid upon the care of the teeth and the mouth, and cleanliness of the skin. The food was of the best. During the cold winter nights the heads of the children were hooded and they slept in rooms with flaps of the tents raised. Sufficient time had not yet elapsed since beginning this work to enable him to give any definite or detailed reports, but some of the results obtained had been remarkable.

Dr. John Winters Brannan said he had watched these cases very carefully during the past summer, and that anyone who had visited and seen what he had would never question the results that had been obtained during the past eight months in the tent camp and hospital of the Association at Coney Island. The Association did not intend to maintain the hospital permanently, but it was the intention to show the profession and the city and state authorities what could be done with cases of surgical tuberculosis. The wonder was that this work had never been done before, and France should be greatly praised for having had such institutions for over forty years. He said that the windows at Sea Breeze were wide open at night; these patients developed such a powerful resistance from the exposure to the fresh air that they could stand such exposures even better than we could. He was unable as yet to speak of final results. The French surgeons did not expect cures within three years. He said that Mr. R. Fulton Cutting had raised the question whether we could say that the sea air was better for these cases than land air. The French had answered this in the affirmative, although the members of the Association were not able to state positively that it was so. There was one thing very important regarding the seashore for such hospitals, and that was the opportunity given for amusements; all the children there were occupied on the beach, were interested in passing ships, played in the sand and in the snow.

Dr. Virgil P. Gibney said he was convinced that the seashore was the place for these children who were suffering from non-pulmonary tuberculosis.

Dr. Charlton Wallace, Visiting Orthopedist to the Experimental Seaside Tent Camp for Tuberculous Children, spoke of his experience in attending to the orthopedic cases, and of the many instances of remarkable improvement. He said he had taken ten weights of ten children at the Hospital for Ruptured and Crippled, with similar lesions, and who remained in that hospital the same length of time as ten children at the Seaside Camp. In making his comparisons he found that the average difference in weight was seven and a half pounds. This proved that the children at the seashore had a greater chance for an ultimate recovery than those at the inland hospital, although at the latter they had the best care and food that could be obtained.

Dr. A. Jacobi said that he believed all appreciated what could be done in tuberculosis by fresh air, exercise, good food, and proper sanitary treatment. He said he did not belong to those who thought that tuberculosis of the lungs, bones, or glands, or general tuberculosis, should be left alone and treated only by the means spoken of. For thirty years or more he had one treatment which was of much service to him, and for fifteen years he had an internal treatment which he added. In 1869 and 1870 Wagner of Berlin proved that fractures of the limbs would unite in a shorter time if the animals upon which he was experimenting were given phosphorus (not the phosphates which were inert). Therefore, in cases of subacute or chronic osteitis, *i.e.* of tuberculous character, he always gave phosphorus, and they all got better and showed a marked improvement. The cases not so treated did not improve so rapidly. For the last fourteen or fifteen years he had given guaiacol as a routine measure in tuberculosis of any kind.

Intramuscular Injection of Insoluble Preparations of Mercury in Syphilis.—Dr. Hermann G. Klotz read this paper. He said that injections of insoluble preparations of mercury within the last fifteen years had become one of the most popular methods of treating syphilis on the European continent, and had largely supplanted inunctions and soluble injections. In this country, up to within the

last two or three years, very few publications on the subject had appeared in the literature, although quite lately they had become more frequent. As a result the profession at large was in ignorance of the progress made by this method. He said he would restrict himself to a general report of his experience with insoluble injections since 1886, and to a consideration of the criticism of the method as found in American literature. The claims made by some enthusiasts, that insoluble preparations when injected were likely to effect a cure of syphilis in the shortest time, and with a minimum amount of mercury, he wished to repudiate. But he believed and expected to prove that in the insoluble injections we possessed one of the most effective methods of bringing the organism infected with syphilis under the influence of mercury, a method, however, destined to supplement rather than to exclude the older methods. Therefore, he had been using and expected to use, the latter in the future, ingestion by the mouth, inunctions, insoluble injections, baths, fumigations, as well as the iodides and even sarsaparilla, besides the insoluble injections according to the conditions of the patients and often depending on external circumstances. Up to the end of 1904 he had records of 2,500 injections made on 204 patients, all made but six, 2,112 of the salicylate, 150 of the yellow oxide, 216 of calomel, and three of gray oil. He included 19 injections of a 5 per cent. solution of bichloride, but the severe local symptoms and greater tendency to salivation caused their early discontinuance. The ages of the patients ranged from 18 to 60 years, and the number of injections from one to forty-two, sometimes distributed over three or four years. The usual dose was one c.c., which represented 10 cg. of the salt suspended in oil or liquid or liquid vaselin. The injections were given at intervals of one week, whenever symptoms of syphilis were present, up to their disappearance; thereafter two to four injections were added at intervals of ten to fourteen days. Ordinarily not more than ten injections were given continuously, except when the intervals had been longer. As the salicylate represented 59 per cent. of mercury, ten injections of 10 cg. within ten weeks were equal to 59 cg., *i.e.* approximately 8 grains of mercury, equal to the maximal dose of 8 blue pills. He did not consider it wise to continue insoluble injections whenever after three or four no impression on the manifestations was made; an intermission of several weeks or months, with iodides or quinine and other tonics, would render the patient much better prepared for the renewal of this treatment. He believed that the lack of success in treatment of those late forms had been due to the insufficiency of the means employed. In his own experience no pain had resulted from the injection nor any flush around the needle puncture nor inflammation of the skin. Among his 2,500 injections he had seen but four abscesses result. Stomatitis was never seen after injections of the salicylate; after calomel injections it sometimes did appear. In a small number of cases enteritis and colitis appeared after insoluble injections. Embolism into the lungs he had observed altogether twelve times; eight occurred up to the end of 1897 out of 1,072 injections, and were published in Professor Pick's *Festschrift* in 1898. Several deaths had been reported among thousands of injections in Europe, and in some he believed them to be due to faulty technique. Among the advantages accruing to the patient, besides the therapeutic effects, were the following: The stomach and mouth were not exposed to the influence of the mercury; the patient was able to attend to his business without interruption; [illegible] and frequent visits to the physician; and he enjoyed long intervals free from treatment.

Dr. Edward L. Keyes believed that the intramuscular injection of insoluble salts of mercury was a distinct advance over the older methods that had been employed, and that as prompt an effect could be gotten as with fumigations with the black oxide of mercury. He had given as much as three and a half grains, three times a week, for two weeks in succession, with distinct effects and without salivation. He was in the habit of using a veterinary syringe with an extra large needle which could suck up the material. He always tried to educate the patient to keep himself constantly in mind, and the advice to continue the use of mercury for at least two and a half years was not to be left out. He believed in starting the patients by getting control of the symptoms early by an injection or two, and then to entrust the patients with the use of some mild form of mercury, having him appear from time to time for observation. He emphasized the fact that it was necessary to obtain the cooperation of the patient. The discomforts of the treatment were far overbalanced by the advantages obtained.

Dr. Prince A. Morrow said he had used only the salicylate of mercury for many years, because this insoluble preparation gave the greatest freedom from irritation, and surely was the preparation of choice. He referred to a paper he had read before the New York Academy of Medicine nearly twenty years ago on the hypodermic use of the mercurial preparations in the treatment of syphilis, taking up both the soluble and the insoluble preparations, and he was struck to-day not only with the advance that had been made in this mode of treatment, but also in the confidence the profession now had in it. Then it was a tentative method, and in the experimental state. To-day the tendency was to attenuate the treatment, and better results were had by so doing. It was his custom to give ten or twelve injections, and he had given as many as one hundred injections in a single case. It was not, however, his custom to use it methodically in the treatment of syphillis, and he looked upon it rather as a reserve treatment. He also used it in those late cases of syphilis where idiosyncrasies extsted for iodides or iodide of potassium; then the substitution of salicylate of mercury by injection was of great advantage. He also used this method of treatment in late syphilis when the patients had not received sufficient treatment in the early secondary stages. Although salicylate of mercury was the agent of choice, there were some cases of late lesions, especially about the mouth, where calomel seemed to do better, having a more marked and prompt effect.

Dr. Eugene Fuller said there was no doubt about the value of the salicylate of mercury used by intramuscular injection in the treatment of syphilis, and he was using it more and more. In some cases mercury by the stomach did not appear to be absorbed at all, and then this method, of course, was very useful. If quick results were desired there was no method that equaled it in bringing the patient under the influence of mercury. He had had but one case in which he had done any damage by the hypodermic method; in this case, with a very marked tuberculous history, he got an embolic effect in the lung, which he believed caused a subsequent outbreak of tuberculosis by its irritating effect. Nowadays if a patient gave a marked tuberculous history he avoided the hypodermic injection of this agent. The profession, as a rule, did not understand the method of giving injections of mercury in syphilis.

Dr. William S. Gottheil said that the most ardent advocates of this form of treatment that we now had were the patients themselves. He said he had never seen any embolic results from these injections.

Rhinoscleroma; With Presentation of Case, Specimens, and Stereopticon Views.—Dr. Max Toeplitz and Dr. Henry Kreuder (by invitation) contributed these communications. Dr. Toeplitz said that the disease, rhinoscleroma, was looked upon more as a curiosity, and at present but 600 cases were known to exist. The patient he presented was a woman, 27 years old, two and three-quarter years in this country. For twelve years she had protracted headaches, which ceased about one year ago. She said she had always suffered more or less from "colds." Eight years ago her nasal breathing became much impaired. She never had any pain in the nose, and her sense of smell was normal. Another member of her family had the same trouble. Four months ago she spat out a piece of flesh. There was

no change in the outer nose. Upon examination of the patient, the left nostril was found to be obstructed by a whitish-gray and exceedingly hard mass. The nasopharynx was the seat of nodular swellings. The uvula was missing. The larynx was free. Dr. Toeplitz gave a brief description of the disease, and said that the spread of the disease, in Europe especially, made it necessary to watch these cases more carefully.

Dr. Henry Kreuder told of the microscopical findings, illustrating his remarks by stereopticon views.

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, held December 27, 1904.

Dr. Henry S. Stearns in the Chair.

Limitations of Office Practice in Rectal Diseases.—Dr. Charles B. Kelsey read this paper (see p. 129).

Local Versus General Anesthesia in Rectal Diseases.—Dr. James P. Tuttle said that the two most important features which distinguished good surgery to-day had to do with anesthesia and asepsis, and that the question he had to consider in his remarks dealt with the comparative merits of local or general anesthesia as applied to rectal surgery. The anus and lower rectum were endowed with an abundance of sensory nerves, and the sensitiveness there was more marked than in almost any other part. The question of analgesia and anesthesia was more important in this region then than elsewhere. The analgesics were local and constitutional, the anesthetics local and general. Among the chief types of analgesics were cocaine, eucaine, carbolic acid, sodium bicarbonate, etc. He was inclined to be rather cautious in the use of opium and cocaine for relieving pain in rectal disease, because of the danger of these patients becoming habitués. After operations opium constipated and tended to make the movement of the bowels more painful. Among the local anesthetics he mentioned carbolic acid, ice, ethyl chloride, cocaine, eucaine, sterilized water injected into the parts, etc. The first three were useful in small operations, but carbolic acid was really the only valuable one among them, giving the most satisfactory results. Experience had taught him that the chief pain from hypodermic injections was produced by the distention of the parts with the fluid used; everything else being equal, the substances which produced the greatest anesthesia per minim in the parts would be the most satisfactory. The great objection to the use of sterilized water for local anesthesia was that the method itself was painful. Again, punctures through tissues which could not be sterilized thoroughly invited infections; punctures and the subsequent distention might cause rupture of blood-vessels and extravasation of blood and interfere with the proper circulation in the parts, causing later on sloughing and possibly perirectal abscess. When the parts were distended one was unable to tell how much tissue was to be removed. This method, too, was absolutely unreliable. In any form of local anesthesia one might get outside the anesthetized area and then would be compelled to stop work to give more of the injection. Another objection to this method was that both surgeons and patients soon learned to underestimate the importance of the operation, the importance of [illegible] technique, and the advantages of rest in bed, as after all operations upon the rectum. Among the possible advantages of this method was that one was enabled to do this work in the office when otherwise it must be done in the hospital or at the patient's home; again it could be used when ether or chloroform was contraindicated; it could also be used in those patients who were afraid to take general anesthetics and who would refuse to be operated upon if this was exacted of them. It was a well-known fact that the pain following the use of local anesthesia in rectal work was greater than that following the use of a general anesthetic. If small hemorrhoids, fistulas, or fissures were to be operated upon, ethyl chloride could be used and the operation completed without having to resort to ether or chloroform; this was especially true if the patient were given a hypodermic injection of morphine five or ten minutes before the anesthesia was begun. If the ethyl chloride was given drop by drop and not sprayed, getting it in concentrated form, the anesthesia would be more complete and be produced more quickly. By the drop method only about 4 c.c. need be used; whereas, by spray one frequently required 20 to 25 c.c. By the use of ethyl chloride one got a greater relaxation of the muscles. By this method he believed that one could do in office practice any operation that was justifiable without pain, and do it unimpeded by any restlessness of the patient. After all had been said ether was the most satisfactory in extensive operations about the rectum; it relieved the pain, caused muscular relaxation, and quieted the patient, all of which contributed to perfect surgical work. In all operations upon the rectum, Dr. Tuttle said, one should bear in mind the intimate reflexes connected with the pneumogastric nerve. Whenever the rectum was stretched the anesthetist should always be advised to remove the mask because of the inspiration produced at the time.

Chronic Constipation: A Rational Treatment.—Dr. Dwight H. Murray, of Syracuse, N. Y., read this paper and referred to the pathological changes that occurred in the rectum, particularly the anal canal, and also to proctitis, sigmoiditis, and colitis. As a rule the pathological changes that were associated with chronic constipation were to be found below the entrance to the sigmoid. His plan of treatment of chronic constipation had not been used by others, and he said it gave him much pleasure to be able to present it to the profession. In taking the patient's history the most careful routine should be followed and certain symptoms should be elicited that would aid in classifying the cases. A thorough examination was necessary; if patients declined to allow such an examination they should be refused treatment. The treatment was given every fourth day, until the patient had daily normal stools; after that time the length between treatments should be increased, until the patient could get along on his own resources. The treatment occupied about one hour. The patient was placed in the Sims position, and an electrode with a perforated soft rubber shield was passed into the sigmoid. This was connected with the positive pole of a battery and also with an irrigator containing decinormal salt solution held three and a half feet above the patient; the flow was readily controlled by a stop-cock. Before treatment was begun, the mucosa should be thoroughly cleansed. The effect of the treatment seemed to be soothing and quieting to the mucous membrane. As a result of treatment the patients had a better power of expulsion than was possible before the treatment was begun. The temperature of the fluid used should be 100° F., and from 5 to 20 milliampères should be used. When the first part of the treatment was finished, the skin would be found to be reddened. No electricity reached the part except through the saline solution. The electricity was applied about ten to fifteen minutes, and from thirty-two to thirty-six ounces of fluid flowed through into the sigmoid. Then the patient was instructed to go to the toilet. Later he returned to the table for the second part of the treatment, when a special tube was utilized to insert into the colon bismuth subnitrate, iodoform, and oil. This was followed by the use of a solution of ichthyol or hydrastis. The patients were kept on the table with the hips elevated for ten minutes. When the treatment was begun they were instructed to discontinue the use of all laxatives, to go to the toilet at certain hours every day, and never to strain. If the bowels at first failed to move, then an enema of plain water and oil was given. The patients were allowed a liberal diet and were told to drink six glasses of water daily. The results of this treatment were that daily and normal movements were produced. Nearly 75 per cent. were cured.

while almost all of the remaining 25 per cent. were improved. Four and a half years was the longest time required in the treatment. Dr. Murray closed his paper by stating that the three greatest causes of constipation were ignorance, carelessness, and laziness, and he believed that a great many people to-day in the insane [illegible] brought there by the results of chronic constipation.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending January 20, 1905:

	Cases.	Deaths.
Measles	194	4
Diphtheria and Croup	360	40
Scarlet Fever	289	14
Smallpox		
Chickenpox	179	
Tuberculosis	194	153
Typhoid Fever	50	12
Cerebrospinal Meningitis		30
Typhus Fever		
Yellow Fever		
Cholera		
Totals	1,476	253

Two Cases of Weil's Disease Complicated by the Temporary Appearance of Small Tumors in the Liver.—M. Einhorn sums up the main features of these cases as follows: In both the diseases began, after a short prodromal stage, with fever, severe gastric disturbances, and general weakness. During the period of fever, which lasted about a week, a marked enlargement of the spleen as well as of the liver was found. Albumin in the urine and the diazo reaction, and a trace of bile pigment, were present in both, whereas sugar was found in one case only. Both had bronchitis. Cerebral symptoms, insomnia, severe headache, and disturbances of speech (some stuttering) were present in one case but not in the other. Widal's test was negative in both, and no plasmodia were found in the blood. Convalescence took place after about a week's illness. In the course of a few days the stomach, kidneys, spleen, and liver appeared to be perfectly normal. Weakness persisted for a time, but passed off in a few weeks, and the patients were perfectly well. The most remarkable fact in connection with these cases was the appearance at the height of the disease of small hard tumors on the hepatic surface and their disappearance with the abatement of the fever. The clinical picture corresponds in the main to the symptom-complex of Weil, with the exception of these transient hepatic nodes. These were probably the result of an acute hepatitis. The nodes may have been caused by an accumulation of exudative products which disappeared with the subsidence of the inflammation. The writer states that in the presence of such tumors in a patient suffering from fever it is better to withhold the diagnosis of cancer or gumma of the liver until further observation permits a definite conclusion to be formed.—*American Journal of the Medical Sciences.*

Orthostatic Albuminuria.—Teissier believes that the othostatic albuminurias should be classified in three different groups: (1) Symptomatic or mixed albuminuria. This constitutes a particular type of residual albuminuria consecutive to infections. (2) Associated orthostatic albuminuria in which to the upright position there are added other causes such as cerebral disturbance and digestive troubles. To this category belongs the syndrome of Pavy. (3) True orthostatic albuminuria, of which there exist scarcely 20 clearly defined observations. This type is seen in subjects of infantilism, with evident nervous heredity and presenting a small heart, and hypotension with hypoplasia of the arterial system. As soon as the patient changes from the horizontal to the vertical position, he voids a cloudy urine, containing mucus, rich in phosphates, and showing on analysis 50 centigrams to 7 grammes of albumin. There are no casts and no excess of urea or of chlorides. According to the writer, when the patient stands upright, a sudden anæmia of the kidney is produced, which favors a narrowing of arterial caliber. Intense congestion from vasodilation follows this anæmia. Albumin then filters easily through an incompletely developed glomerular apparatus. These distinctions have not alone a theoretical importance, for true orthostatic albuminuria tends to disappear spontaneously in proportion to the development of the organism. Its disappearance will be facilitated by the use of hydrotherapy, aërotherapy, and exercise.—*Gazette des Hôpitaux Civils et Militaires.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague, have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended January 20, 1905:

SMALLPOX—UNITED STATES.

			CASES.	DEATHS.
Alabama, Mobile	Dec. [illegible] to Jan. 6		3	From vessels in port.
Arkansas, Fort Smith	Dec. [illegible]-17		1

SANITARY CONDITIONS AS ENCOUNTERED IN CUBA AND PANAMA, AND WHAT IS BEING DONE TO RENDER THE CANAL ZONE HEALTHY.*

BY WILLIAM C. GORGAS, M.D.,
COLONEL AND SURGEON UNITED STATES ARMY.

I WILL not dwell, to any great extent, upon the sanitary conditions of Cuba. They are pretty well known, and I do not think they would interest this audience as much as conditions at Panama; and the cause of our interest in Cuba was entirely different from those that now arouse our interest at Panama.

For two centuries the United States had been more or less scourged with yellow fever, which had generally been imported from Havana. Besides the loss of life, the commercial losses had been enormous. At the time of our occupation of Cuba, there was a perfectly cast iron commercial quarantine against the West Indies, in all the Gulf ports, during every summer; and every few years, when yellow fever, in spite of these precautions, would get into the United States, there would be the same inflexible quarantines between the various States along the Gulf coast and the various cities of that section. We had believed, for a generation or two, that if, in any way, we could get rid of yellow fever in Havana, yellow fever would cease to be a menace to our Southern States. So that, practically, the sanitation of Cuba centered about the sanitation of Havana; and the sanitation of Havana, in our mind, consisted almost entirely in sanitation with regard to yellow fever. We then believed that if any disease was caused by filth yellow fever was that disease; and all our thoughts and all our efforts were centered about cleaning up.

For over two years we cleaned most industriously. I do not think there ever was a city in the history of the world that for two years and a half was so industriously swept, scrubbed, and cleaned from one end to the other, and from top to bottom, as Havana was. As I look back upon it now, I am inclined to agree with the estimate that the natives put upon us.

I one day went into the patio of a large tenement house that was being fumigated, scrubbed, cleaned, and whitewashed from top to bottom. Some thirty or forty men were hard at work doing this in the most industrious manner. The poor people had all their belongings placed out in the patio, and were themselves sitting about in the most uncomfortable and disconsolate way. As I was standing looking on, a man who had evidently just come in and did not understand what was going on, asked his wife what it all meant. She replied, in a good-natured way, that she did not know, but that it was "just one of the ways of those crazy Americans." Her good nature made quite an impression upon me. She evidently had no particular sympathy with what we were doing, but had a general idea that we were trying to do it for their good, notwithstanding that she considered it as one of our extreme and crazy ideas; and, as things turned out, she was nearer right than we were.

In time, Reed's Army Medical Board came along and made the astounding discovery that the mosquito alone conveyed yellow fever, and that dirt and filth had very little, if anything, to do with the question.

My good friend Dr. Finlay, whom I am glad to see here with us to-night, some twenty years before had advanced this same theory, and during the twenty years preceding our occupation of the island had written and advocated the theory continuously. I had often heard him expound his views on the subject, but, like the Cuban woman, I smiled in a superior way at the "crazy Cuban doctor." But Dr. Finlay has had the good fortune (such as has fallen to few great men) to live to see his theories recognized and adopted by all the world.

Even after the discovery of the cause of yellow fever, it did not seem that we were any nearer the prevention of the disease. Though we knew that the mosquito was the cause of the disease, no feasible way of putting this knowledge to practical application was evident.

It is not generally known that our first practical tests were in the way of inoculation and not a mosquito destruction. We thought that the most successful thing would be to give people mild attacks of yellow fever by biting them with infected mosquitos, and thus, gradually and safely, make all newcomers immunes by giving them the disease. We attempted it on a large scale, established an inoculation station and went to work; but three fatal cases early in our operations showed us that the method was exceedingly dangerous and that we would have to give it up.

We then turned our attention to mosquito destruction in its various forms, and screened those suffering from yellow fever and suspects of all kinds; and in this we had the most unexpected and remarkable success. In less than a year, the city was entirely free from yellow fever; and since September, 1901, now more than three years ago, not a single case of yellow fever has originated in Havana. Since May, 1902, the Cubans themselves have carried on this work, under the able direction of Dr. Finlay, who is at present the Chief Sanitary Officer of the island; and it is due to their excellent care and management that the disease has not been reintroduced. Dr. Finlay can tell you that almost every month they get a case or two of yellow fever coming by ship from some one of the infected ports around them, and that they bring the patients to the yellow fever hospital, right in the heart of the city, and there care for them. They simply screen the sick person so that no Havana mosquito can bite him, and, with this simple protection, they take care of the patient exactly as we in the United States would

*Read before the Fourth Pan-American Medical Congress, Panama, January 3-6, 1905.

care for a case of typhoid fever and fear it no more than we do typhoid fever.

We came to Panama primarily to build the Panama canal, and the sanitary department is established for the purpose of carrying through this work with as little loss of life as possible. The history of the work of construction of the railroad and of attempts at the canal has been darkened by an excessive loss of human life. We hope greatly to lessen this loss, if not entirely do away with it.

In looking back over the history of the Isthmus as far as we can get reliable statistics on the subject, malaria and yellow fever have played the greatest part in the mortality. So far as yellow fever is concerned, it seems to me that the problem is not so difficult as it was at Havana; and I believe that, with reasonable effort and reasonable expenditure of money, we can accomplish in Panama and Colon the same results as were accomplished in Havana and by much the same methods.

If we had only the same knowledge of yellow fever in coming to Panama that we had in going to Cuba in 1898, I would look upon yellow fever as much the most important disease of the two, from a sanitary standpoint; but, with out present knowledge of the subject, I dismiss it as settled that we eliminate yellow fever. If we do not, some one will certainly be at fault and should be held strictly accountable for it; and I have not the least doubt in my mind but that the guilty individual will have an exceedingly lively time of it.

But malaria on the Isthmus and malaria at Havana are very different problems. Malaria, in a big city, is principally a disease of the suburbs; and as the breeding places for Anopheles are not very extensive in the suburbs of a large city, the work of eradicating these breeding places is not so great a problem. And even when Anopheles are bred, only a small part of the human population is infected; so that a good many mosquitos will bite before one happens to strike an infected individual and thus get the contagion. While our efforts at Havana were not directed particularly against malaria, the same work that destroyed the yellow fever mosquito at the same time destroyed the malaria mosquito; and we practically eliminated malaria from Havana without particularly intending so to do, by the same works that got rid of yellow fever—simply the destruction of the breeding places of the Anopheles mosquito.

But on the Isthmus I find conditions very different. We have a long line of canal with twenty odd villages and some twelve thousand people scattered over a length of nearly fifty miles. We find that most of these twelve thousand people are capable of conveying the contagion of malaria to any newcomer who comes to live among them. By actual microscopical examination of the blood of several hundred of these people, we find that over 70 per cent. have the malarial parasite circulating in their blood; and this on a single examination. The percentage would probably be very much higher if we made a second or third examination of the 30 per cent. who are found uninfected at the first examination.

This means that practically every female Anopheles mosquito that bites a human being along the line of the canal becomes infected, and our examination has further shown that there is no lack of Anopheles mosquitoes. I suppose it is no exaggeration to say that any man who spends a night in one of these villages will contract malaria.

Our examinations have further shown that the kind of parasite discovered in these cases is not the parasite of the ordinary chills and fever, known as the tertian and quartan, but the parasite that causes the deadly Chagres fever, known as the estivo-autumnal parasite. Probably 80 per cent. of the infected individuals examined were infected with the Chagres or estivoautumnal parasite. This will give you some idea of the conditions as to malaria which we are attacking.

Our plan along the canal is, in general, as follows: To eliminate all possible breeding places for Anopheles near villages or dwellings along the canal. This we expect to do principally by superficial drainage. As you see in going over the railroad, we have already made considerable headway in this direction. I think any one who has never tried it would be surprised at the effect a little work around an unhealthy locality will have in doing away with the different species of mosquitos that are night travelers, such as the Stegomyia and Anopheles. Ancon Hospital, which six months ago was a pretty bad mosquito locality, is almost entirely free. At my own quarters, I scarcely ever see a mosquito.

We are also going to try to do all we can towards freeing the inhabitants along the line of the canal at present infected, from the contagion. We are establishing, as rapidly as we are able, dispensaries at various points, under the charge of competent physicians, who will treat natives and endeavor in every way possible to get them to take quinine regularly.

By these two methods, viz., by decreasing as much as possible the number of malaria-bearing mosquitos, and, on the other hand, by decreasing as much as possible the number of instances of malaria-infected natives, we hope to bring it about that when the large influx of laborers comes to the canal there will not be so general a malarial infection among the newcomers as there was among the French, for instance, in the days gone by.

If in Havana, by mosquito work alone, we practically succeeded in eliminating malaria, or if at Ismailia, on the Suez canal, under the advice of Dr. Ronald Ross, by mosquito work alone, malaria was entirely stamped out, I feel very confident that, by the two methods combined, we ought to have a considerable degree of success at Panama. If, on the one hand, we could get rid of every Anopheles along the line of the canal, and, on the other hand, cure every human being of the infection, we would surely be entirely successful and have no malaria at Panama. While, in all probability, such complete success is not possible within any short time, we will approximate this idea of a perfect condition just in proportion to the amount of labor and money we are willing to spend in the attempt. Personally, I approach the problem with great hope of success.

While this malarial question is a great and overshadowing sanitary problem at Panama, many other things have to be attended to as important adjuncts in the sanitary department—things that, if left undone, would bring upon us calamities far greater than malaria. We have organized, under the able and skilful management of Dr. H. R. Carter, of the Public Health and Marine Hospital Service, a most efficient maritime sanitary service. With this service in full operation, as it is at present at both Colon and Panama, I feel reasonably certain that infectious diseases from the outside will not be introduced. On the Pacific side, on the West coast of South America, we have many ports infected with plague and several infected with yellow fever, from which it is Dr. Carter's duty to see that we do not import those diseases. On the Atlantic side, both above us and below us, we have yellow fever infected ports; and, as most of our immigrants come through

the port of Colon, Dr. Carter has to keep a vigilant eye open to see that no smallpox is introduced.

The Panama government, by degree of President Amador, has made me the Health Officer of Panama and Colon, and authorized me to make such sanitary regulations as may be necessary to enforce proper sanitation in these towns. Dr. Balch, Health Officer of Panama, under this decree, is organizing a health department for the city of Panama; and Dr. Spratling, under the same authority, is doing the same for the town of Colon.

Along the Zone, where the mosquito work is all important, Mr. Le Prince has already organized a very efficient mosquito service. Mr. Le Prince organized and carried into effect our mosquito work at Havana.

Four-fifths of the expenses of the sanitary department are concerned in the care of the sick. The Commission, as a sanitary measure, has wisely determined to care for all the sick of Panama, Colon, and the Zone. This important service is being organized by Dr. John W. Ross of the Navy, and his department has charge of all the hospitals, dispensaries, and everything pertaining to the care of the sick. We have under way at present a 100-bed hospital, on the island of Taboga, a most salubrious and attractive location, where we expect to care for the severer cases, during convalescence and thus make room at the hospitals on the mainland.

At Ancon Hospital, in the suburbs of the city of Panama and located on the side of Ancon Hill, we have our principal hospital, which is at present in active operation under the superintendence of Major La Garde, of the Army.

At Miraflores, we have a 100-bed hospital for chronic cases, insane and lepers, under the care of Doctor Bates.

Along the line of the canal, we have three smaller hospitals, at Culebra, Gorgona, and Bohio, under the charge of competent medical officers.

At Colon, we have a hospital in operation which, in a short time, we expect to have equipped with 300 beds.

Beside these hospitals, we have several dispensaries at other points along the line, under the charge of various medical officers.

In the grounds of Ancon Hospital, we have a general laboratory, under the direction of Drs. Herrick and Kendall—both Johns Hopkins men, well equipped for the work and for such laboratory investigation as is cognate to sanitary work. As it goes on and we see our opportunities for extension, we hope to develop the laboratory work into a more general field of tropical investigation; and in this way we have great hope of doing something that may be of general interest to the medical profession at large.

I think I have now given a brief outline of the subject on which I was asked to talk to this meeting. At present I can only point out what we hope to accomplish and what results may reasonably be expected to come from our efforts. A year or two from now, I hope I may be able to write another paper on the subject of what has been accomplished at Panama in the way of eradicating malaria and yellow fever, and I trust that a comparison of the two papers will not show too great a discrepancy between my hopes and my realizations.

Cancer in Men and Women.—The records of Middlesex Hospital, London, show that cancer in women gradually increased from 1746 to 1874. It has since maintained a constant level. On the other hand cancer in men has steadily increased from the beginning. The records of St. George's Hospital show a similar fixed level in women and one that is still rising in men.

INTRAMUSCULAR HEMORRHAGE FROM MUSCULAR ACTION.*

By ANDREW H. SMITH, M.D.,
NEW YORK

I HAVE selected the above title for the following paper in order to emphasize the sharp distinction to be drawn between those cases in which the escape of blood within the intact sheath of a muscle is the important factor, and those in which laceration of muscle and sheath plays the principal part.

While at first sight the latter sort of cases should be the more formidable, the former sort may give rise to greater immediate suffering and more lasting impairment of function.

That muscular fiber may be ruptured by the violence of its own contraction is a fact very frequently illustrated. This rupture may be confined to a few fasciculi, or it may extend entirely through the muscle, dividing it transversely into two parts. Again, it may be within the fascia enveloping the muscle, the fascia remaining intact, or it may involve both muscle and sheath. In the first case the resulting hemorrhage will be confined within the sheath; in the second, it will spread into the adjacent intermuscular spaces and into the subcutaneous cellular tissue, and a hematoma will result. While of course the liability to rupture is increased when the integrity of the muscular fiber is for any reason impaired, yet such ruptures do take place not only in perfectly healthy muscle, but even in muscles specially developed by training or by occupation.

While almost any muscle may be the seat of rupture some muscles are much more exposed to this accident than others. Those that act through the tendo Achillis present more cases of this kind than any others in the body. This is probably due to the immense strain to which they are subjected. In ordinary walking there is a movement with each step when the entire weight of the body is supported on the ball of one foot. At this moment the foot acts as a lever of the first class, with the power applied to the short arm, which has only one-third of the length of the long arm. The strain upon the tendo Achillis is therefore three times the weight of the whole body, or for a person weighing 175 pounds, 525 pounds. This strain, however, is easily borne if it is applied somewhat gradually, but if the strain is brought to bear suddenly the tendon may be ruptured or some of the muscular structures which act through it may give way.

Incoordination of the fibers of a muscle also may cause some of them to rupture. In such cases the muscle is, as it were, surprised into sudden action, and the motor impulse is not distributed to all parts of it simultaneously. Excessive stimulation and irregular contraction of certain fibers or fasciculi cause them to give way. In this way, probably, we are to explain those cases in which there is no conscious muscular effort at the moment of the accident to which the rupture could be ascribed. Such cases are designated by French writers under the name "coup de fouet," in allusion to the sudden stinging pain with which they are accompanied. This coup de fouet is well illustrated by one of the cases to be described presently.

The amount of hemorrhage which these accidents give rise to will depend more upon the freedom with which the effused blood can escape into the neighboring tissues than upon the size of the vessels torn across. In the case of the calf we have an exceedingly tough, wholly inelastic fascia or aponeurosis which is blended with the periostum covering the anterior surface of the tibia and extending

*Read at a meeting of The Practitioners' Society of New York, January 6, 1905.

laterally and posteriorly envelops completely the entire mass of the leg muscles. These muscles are therefore enclosed in a closely fitting unyielding sack closed everywhere except where the deep vessels of the leg enter and emerge. It is evident, therefore, that blood effused into this sack cannot escape from it if the sack itself is uninjured, and that consequently the hemorrhage must be limited to the amount the sack will contain over and above its normal contents, even if it is not sooner arrested by the hemostatic effect of pressure.

Now if the blood escapes slowly from a small orifice into a relatively large sack, it is plain that the principle of the hydraulic press will come into play, and that a very considerable tension will result. That this pressure should cause extreme pain is only to be expected. It is described as like that of a continuous cramp. The conditions of nerve involvement in a given case will, of course, exert a modifying influence upon this pain.

Blood confined in this way beneath the deep fascia of the calf gives rise to a smooth, tense tumor in the situation of the effusion. This may be masked after a while by edema of the subcutaneous cellular tissue, the result of obstruction of the return circulation by the pressure upon the posterior tibial veins.

The ultimate destiny of a clot imprisoned in this way would be that of blood effused in any situation, where it is protected from infection, as, for example, in intracranial hemorrhage. The more fluid portion is absorbed, and the remainder undergoes imperfect organization.

The following case illustrates the results of an effusion of blood within the deep fascia of the calf. A lady about 38 years of age, in good health and weighing about 170 pounds, while passing the summer at the seashore, was stepping from her carriage —a low victoria—when at the instant that her whole weight was supported upon the left foot, the right foot not having reached the ground, she was seized with a sharp pain in the left calf, wholly disabling the limb and causing her to fall.

She was removed to her house and carried to her room. Half an hour later I found her lying upon a lounge and complaining of much suffering. The leg was but little swollen, but in the situation of the gastroenemius a somewhat tense tumor could be felt which shaded off into the surrounding tissue. This tumor was extremely sensitive to pressure. There was no palpable rupture of the muscle, no groove or sulcus across it such as I have seen in other cases. The limb was completely limp from the hip down, the patient refusing to make the slightest effort to move it.

The patient was placed in bed with the body turned partly toward the left side, and the hip and knee flexed. Ice was applied to the calf and a moderate anodyne was administered. By this time it was evening, and the whole night was passed in pain and discomfort, only snatches of sleep being obtained from which the patient was wakened by spasms of pain.

The following day was passed more comfortably, but the extreme disability remained unchanged. The support of a bandage was tried with little or no benefit. The slightest movement of the limb caused an access of pain, and the patient objected strenuously to everything that involved the least disturbance.

Thereafter as the days passed on, the pain became less, so long as quiet was observed. But weeks elapsed before the foot could be allowed to touch the floor, and it seemed as if the patient were doomed indefinitely to divide her time between the bed and the divan. There was no ecchemosis nor any constitutional disturbance. The deep-seated swelling scarcely changed appreciably. Moving even across the room could be accomplished only on crutches. Elastic appliances of various sorts were tried, but seemed to increase the discomfort rather than to relieve it. An eminent surgeon from New York was summoned in consultation, who confirmed the diagnosis of hemorrhage within the muscle and recommended that a supporting apparatus of sole leather should be moulded to the leg, and worn whenever the patient was out of bed. A famous maker of such appliances was sent down to take the measurements, and after several days the apparatus arrived, and was adjusted to the limb. But after a few trials it was laid aside.

Meantime the entire summer had passed, and when she returned home at the end of the season the patient was still very lame. She was then wearing a plaster bandage. Later, massage was employed. At one time, near the close of the treatment, a metallic brace was adjusted to be worn when awake. The entire duration of the treatment was about three months, when the case ended in complete recovery.

Within a few days of a year ago, a gentleman of about 45 years of age, in excellent health, was standing on the platform of the elevated railroad at a downtown station, waiting for a train. As the train approached he simply turned toward it without being conscious of any muscular effort whatever. As he did so, he felt a very severe pain in the left calf, as if, as he described it, a blunt pointed instrument had been thrust at him with much force, or he had been struck by a spent bullet. With great difficulty he gained a seat in the train, and with the pain constantly increasing, he reached the station at 42d Street. The leg had now become completely incapacitated, and he was glad to accept the assistance of a gentleman who supported him onto the platform and down the stairway to a carriage, which conveyed him to his house. Hot fomentations were then applied, which relieved the pain somewhat, but it was still so severe on my arrival, half an hour later, that I gave him an anodyne. On examination, the aponeurosis enclosing the calf muscles was felt to be tense, and the calf was very tender on pressure. There was, however, no palpable rupture of the muscle, and no hematoma. Later there was slight diffuse edema of the subcutaneous areolar tissue. When the limb was placed in a position to relax the muscles of the calf the pain became endurable, but when the leg was dependent, and especially upon every attempt to bear weight upon it, the pain became intolerable and caused a sensation of faintness.

The patient was put to bed with the knee flexed and supported and the ankle extended. A hot water bag was applied to the calf, and with the aid of the anodyne some measure of comfort was secured for the night. But in the morning, the moment the foot was placed upon the floor, the pain became again extremely severe. For several days, a reasonable degree of comfort was obtained while sitting in a chair with the foot raised and the knee bent, but toward the end of the first week the pain became more constant, and was described as having a tensive character, like a continuous cramp. The swelling increased, but was held in check by a roller bandage applied from the toes to the knee.

In the second week daily massage was begun. It readily removed the superficial swelling, but this gradually returned when the foot was allowed to rest upon the ground. Deep in the substance of the muscle an ill-defined lump about an inch and a half in diameter could be discovered. It was moderately

hard, tender on pressure, and could not be "rubbed away" by manipulation. This tumor, though reduced in size, persists to the present moment, and evidently occupies the position of the original lesion. At no time has there been a depression or sulcus such as marks the seat of a rupture of muscles. I incline, therefore, to believe that the lesion was chiefly vascular, and that the pressure of the effused blood within the unextensible sheath of the muscle was the cause of the extreme pain.

In the present case massage was resorted to pretty freely after the first week. It was found quite easy to dissipate the superficial edema, but it returned when the dependent position of the limb was resumed. The deep swelling could also be reduced somewhat, at least the tension of the deep fascia became a little less by manipulation. But the gain was very transient, and the cramp-like pain soon returned when the foot was placed upon the ground. It was 21 days after the receipt of the injury before the patient could be driven in a carriage to his office, crutches being used in going to and from the vehicle. Even after that time, the progress was very slow, and the condition of the leg very changeable.

It seemed to me sometimes that on the day following a massage the condition was distinctly less favorable. I became satisfied that prolonged massage, frequently repeated, retarded rather than hastened recovery. I came to the conclusion that there was a clot of blood at the point of injury in which organization was trying to take place, and that the formation of the delicate vessels in the clot which is a necessary step in the process was interfered with when the tissues were vigorously manipulated, thus in a measure defeating the reparative effort of nature. I am still of this opinion, and think that, notwithstanding the high place massage occupies in the esteem of the profession as procuring the removal of the "products of inflammation," its use under conditions like these should be very guarded. Later, when vascularization of the clot is well established, massage will hasten the removal of superfluous exudate.

There are authorities, however, who recommend massage at a very early period, even on the first or second day, and that, too, when the laceration of muscle has been free and the escape of blood into the tissues considerable. It is, perhaps, in such cases more appropriate, as by it the blood is diffused and its absorption facilitated. On two occasions, about four and five months after the injury a clay mixture was applied and allowed to remain for 36 hours. This is practically the treatment with wet clay so much in vogue, a few years ago, for promoting the absorption of chronic deposits. It seemed to be beneficial in some degree, but the inconvenience attending its use was such that it was not persevered in.

The present condition of our patient now more than eleven months after the injury is that he can walk fairly well and without serious discomfort for the distance of one or two miles, after which the leg feels "heavy" and marked weariness is rapidly induced. There is, however, a great difference observable in regard to this at different times, on some days the leg giving out after relatively little use, while on other days it is good for a considerable stretch. There is no explanation at hand for this difference, which is the cause of considerable worry and discouragement to the patient. Recently he has begun the use of an elastic stocking from which he derives benefit.

In contrast with these two cases, in which I assume that a limited amount of blood was effused into a confined space, with the result of causing much pain and protracted disability, I will refer briefly to two other cases in which the muscle was torn completely across, but in which the suffering was comparatively slight, and the disability of short duration. One of these cases, like the two already cited, affected the calf, in the other the lesion was of the sternal portion of the sternocleidomastoid.

A gentleman about 55 years of age, and in good health, was bathing in the surf after a storm when the waves were high. As each wave struck him he offered his shoulder to it, bracing himself against the shock with one knee slightly flexed and the other limb firmly extended. While in this attitude an unusually heavy wave came in, requiring a strong effort to resist it, and he felt something give way in his leg, which immediately became helpless.

He was helped to the bank and to the hotel, where I found him within an hour. The calf was swollen, and there was a moderate soft hematoma. Through this a rent across the gastrocnemius could be readily felt, making a gap an inch or more in width, at the junction of the lower and middle thirds of the muscle. There was a good deal of numb pain present, but not nearly so severe as in either of the previous cases.

The treatment was postural, aided by cold applications and support. There was much ecchymosis for a week or ten days. Patient remained in bed for about eight days, when he went about, first in a wheel chair, then on crutches, and finally with a single cane. After the second day there was no complaint of pain while the leg was quiet, but patient was not inclined to move it. Gradually, however, motion was resumed, and day by day the effusion was absorbed, leaving the edges of the rent more defined. These became rounded off as healing progressed. Healing by ligamentous union was complete in about five weeks, leaving a deep permanent sulcus in which the index finger could be laid.

The other case of complete rupture was that of a lad of about ten years of age, who in running up the steps of the house when called to dinner, stumbled and fell forward. He made a very strong effort to recover himself, and in doing so felt a sudden and severe pain in his neck. He took his place, however, at the table, concealing the pain he was suffering, but finding that he could not "hold his head straight," he retired to his room and lay down on the bed. When I saw him shortly after, there was a moderate fulness in the left anterior quadrant of the neck, caused by an escape of blood into the soft parts. Through this a complete rent of the sternal portion of the sternocleidomastoid muscle could easily be felt, about 1½ inches above the attachment to the sternum. The separation was a full finger's breadth.

The patient was placed in bed with the head so supported as to relax the injured muscle, and an ice bag was applied. The complaint of pain was not great. Ecchymosis appeared the following day, but was not extreme. Patient remained in bed for two weeks, the head being supported by pillows and bandaging. Repair progressed favorably. In four weeks he was going about, walking with great care, and often supporting his head with his hands. Two weeks later he was practically well. The union was ligamentous, and ten years afterwards the sulcus was still plainly palpable.

18 East Forty-sixth Street.

A Gruesome Procession.—The medical students at Greifswald, Germany, are said to have celebrated New Year's Eve by parading the streets in a torch-light procession. The torches consisted of human thigh bones soaked in tar, and a skeleton carried by two students headed the procession.

A REVIEW OF SOME RECENT PAPERS ON THE SURGICAL TREATMENT OF PROSTATIC HYPERTROPHY.

By E. G. BALLENGER, M.D.,

ATLANTA, GA.

The rapid strides made in prostatic surgery have brought forth numerous articles advocating various methods of attacking the hypertrophied prostate. Their multiplicity makes it very confusing for one to decide what is the most advisable method, even when all the literature on the subject is available. So recent are many of the important features that no textbook gives the desired information. Many valuable and exhaustive articles have appeared within the last few months, and it is to give a brief review of these, with their essential and unique features, that the following paper is written. The limited scope of this paper will not allow more of a historical review of the surgery of the prostate than is necessary to show the evolution of a once most confused subject to the rational methods of disposing of the hypertrophied prostate now adopted by the leading surgeons. This has been discussed in a most satisfactory manner by Watson[1] of Boston, and Deaver[2] of Philadelphia, in recent articles, from which I have obtained many valuable points. The prostate was discovered in the 16th century by Nicholaus Massa, and it was in the next century found by Riolanus to cause obstruction to the passage of urine. The ancients considered hypertrophy of the prostate an excrescence of the neck of the bladder, and the first attempts at relief were, naturally, through the penile urethra.

The Bottini Method.—In prostatic surgery, the pioneers of the last century were Leroy d'Etiolles[3] and Guthrie[4] (1832 to 1836), the former advocating incision and scarification of the prostate through the urethra, and the latter established the procedure of snaring the projecting middle lobe. Mercier, in 1837, devised a special instrument to be used as our urethrotomes of to-day. Leroy d'Etiolles and Civiale claimed priority. Mercier revived this method in 1856 by devising an instrument, the prototype of Bottini's, which was introduced in 1873 and improved in 1877. It was a galvanocautery instrument, and gained little headway until 1897, when modified by Freudenberg; then it came into favor in France, and, to some extent, in America, where it had very enthusiastic advocates, but limited in number. It has never gained much of a foothold in England. Hugh Young (1902) modified it by supplying blades of different sizes, and Tenney, in 1904, showed an instrument with endoscopic attachment to see the application of the cautery, and thus has evolved our modern instrument.

Perineal Operations.—The various methods devised for incising, tunneling, or removing the obstructing portion through the perineal urethra came into favor earlier than the suprapubic route for in removing stones, polypoid growths were occasionally accidentally excised or twisted off. Guthrie (1836) was the first to establish a regular procedure of incising "the bar at the neck of the bladder." In 1874 Gouley began to use Mercier's galvanocautery through the perineum. Later Harrison advised tunneling the obstruction by the same instrument, but long ago John Hunter, Brodie[5] and Home had tried tunneling with a sharp instrument, but it was abandoned as a very dangerous method. Others devised special galvanocautery instruments to be used through the perineal route. Among them may be mentioned Watson, Wishard, Norton and Chetwood.

Billroth, in 1867, was the first to do a total prostatectomy, but it was for cancer. Gouley[6] (1873) first outlined and executed a plan for a complete removal of the enlarged prostate. Harrison advocated removal of obstructing masses. Leisrink,[7] in 1882, did a total extirpation through the crescentic perineal incision of Celsus and advocated by Zuckerkandl. This was for malignant disease, and the divided ends of the urethra were sutured. Dittel[8] (1890) proposed a different approach, making the incision from the coccyx forward around the rectum and through the middle of the perineum. He removed a wedge-shaped portion from the sides of the gland. Goodfellow (1890) began systematic perineal median urethrotomy incision, and in 1895 Norris incised the capsule of the gland in the mid-line, but did not open the urethra. Parker Syms, Lydston, Delbet, De Pezzer, and Young introduced tractors and instruments. In 1901 Albarran[10] advocated a median perineal incision into the urethra, into which the finger was passed to pull down the prostate. Murphy[11] (1902) introduced hook retractors for depressing the gland. Instead of the instruments for holding the prostate steady and depressing it, as were later devised, Nicoll[9] (1894) used a suprapubic cystotomy incision in order to press the gland down, but he did not open the urethra. Bryson, in 1899, advised incision down to, but not into, the bladder.

Suprapubic Route.—In 1827 Ammusat[12] removed the middle lobe with scissors through this route. Bellfield, in 1886, also did the same operation, but McGill of Leeds was a more ardent advocate of this method, which he adopted in 1887. Fuller[13] suggested counter pressure on the perineum and an incision into the urethra for better drainage. In 1889 Guiteras suggested the method of Pierre Franco (1570), of lifting up the gland with two fingers in the rectum and the thumb on the perineum. In 1901 Mr. Freyer advocated the suprapubic route for total removal of the gland, with or without injury to the urethra.

Indirect operations have been castration, advocated by White[14] (1893); ligation of the vasa differentia (1894), Mears[15]; vasectomy (1893), Harrison; angioneurectomy (1895), Albarran; ligation of the internal illiac artery (1895), Bier[16]; prostatopexy (1902), Delagerniere, etc. All of these methods have been shown futile or dangerous and uncertain. Watson divides prostatic surgery into two periods. Before 1890, characterized by the early development, and after that date, the active period. Formerly much opposition was advanced against surgery of the prostate, notably by Thompson of England, Guyon of France, and Socin of Italy. Since 1890 opposition has disappeared among intelligent surgeons.

The *Etiology* is still shrouded in mystery, and no theory has satisfied all the demands. Ciechanowsky, in 1896, advanced the idea that hypertrophy was an effect of gonorrheal inflammation of the prostate, and the fundamental facts advanced by him have been verified by Brooks and Green[17], and Crandon[18], but Keyes, in a recent article, shows that the theory is entirely lacking in clinical support. Alcoholic and gouty high livers are more likely to have hypertrophy of the prostate, and excessive sexual indulgence is both asserted and denied as a cause. The condition is comparatively infrequent in the negro, Chinese and Japanese. It is rare before fifty years of age that much inconvenience is caused, but from its subsequent growth one must admit that the enlargement had been gradually increasing for a considerable period before that time. It very infrequently makes its first appearance later than the seventieth year. There are two modes of growth, either a tumor formation or a general enlargement of the gland, which in itself shows no one cause is suffi-

cient, and that there is probably a combination of factors which determine it (inflammation, infection, and senility—Crandon).

Anatomy.—Under this heading only a few points will be mentioned. Mr. Freyer[19] believes correct the fact, shown by Sir Henry Thompson forty years ago, that the prostate, until the fourth month of fetal life, consists of two separate lobes, which later unite around the urethra, and that the so-called third lobe in reality is a projection from the lateral lobes into the bladder, or rarely from the commissure between them. Each of these is enveloped by a thin, strong, fibrous capsule, which constitutes the true capsule of the gland, and is intimately connected to its substance. The prostate is further incased in a sheath formed by the rectovesical fascia, in the layers of which are the plexuses of veins. There are bands of connection, however, between the capsule and the sheath, but it is in this "plane of easy cleavage" that the enucleating finger must keep to avoid hemorrhage. This sheath also prevents extravasation of urine into the surrounding tissue after the operation. Mr. Freyer compared it to an orange, the inner thin fibrous tissue covering the segments and intimately connected to the pulp corresponds to the true capsule, while the rind represents the outer sheath, and it is this that is left behind in enucleating the prostate.

Pathology.—Mr. Walker[20] of London classifies the glands into those which remain wholly within the sheath (this sheath covers the entire gland, except at its basal attachment to the bladder and at its extreme apex), and do not project into the bladder, and those which project more or less through the vesical sphincter (the majority take this route) and have an extra—and an intra—vesical portion, separated by a groove made by the sphincter vesicæ. The glands assume an infinite variety of shapes, and may form the main obstruction along the urethra, from the pressure of the lateral masses, or a tumor projecting into the urethra, or into the bladder, or the enlargement may be chiefly back toward the rectum. Hypertrophy of the lateral masses often draws a fold of mucous membrane across the vesicle urethra, forming the so-called "bar at the neck of the bladder." The prostatic urethra is lengthened, and may be dilated and contain a small amount of urine. The bladder wall loses its tone, urine is retained, undergoes ammoniacal decomposition, and cystitis follows. Compression of the ureteral orifices may prevent the normal discharge of urine, and, interfering with the circulation in the kidneys, almost invariably sets up degenerative changes. Later the ureters may dilate and infection take place, with, perhaps, a pyelonephritis. The bladder either dilates and its wall becomes thin and pouched, or it may contract, and the wall will be thick and rugous. Usually with the adenomatous changes in the prostate will be a dilated bladder, and if the prostate is hard and fibrous, the bladder will be of small size and have a thick wall. Enlargement, when once begun, invariably produces residual urine, and often complete retention.[21] Calculi and hemorrhage are of not infrequent occurrence.

Symptoms.—Frequent urination at night is usually the first symptom, and there is often difficulty in starting the urine, and in expelling it the stream has very little force, and there is dribbling at the end of the act. The trouble may run along without causing much inconvenience, until some indiscretion sets up complete retention, and the bladder becomes very much distended. There may be later frequent urination from the overflow of retention. An inflamed bladder may also cause frequent passage of urine. Introduce a soft catheter, coudé or bicoudé, noting any obstruction, and its distance from the meatus; also the distance from the meatus to the bladder, which is usually much lengthened. Observe if there is any deviation from the normal course of the urethra. Never draw off *all* the urine in cases of *chronic retention*, as it may cause immediate death. Examine the prostate through the rectum, without removing the catheter, to determine its shape, size, density, irregularities of any kind, and the condition of the bladder wall, if thin, pouched, and dilated or thick and contracted; also try to estimate the amount of prostate protruding into the bladder, the firmness of its attachments, etc., all of which are matters of importance in deciding upon an operation. In passing the catheter into the bladder, remember that the obstructions occur on the posterior and the lateral walls of the urethra, therefore the catheter should be kept along the anterior wall (Murphy). Measure the amount of residual urine from day to day, or from one complete catheterization to another.

Diagnosis.—The diagnosis must be made from atony of the bladder walls, cystitis, urethral stricture, vesical calculus, tuberculosis and carcinoma of the prostate. By bearing in mind the above symptoms and by a careful rectal examination there need be few errors in the diagnosis, except from carcinoma; this, however, is more difficult and of more frequent occurrence than supposed. Mr. Freyer[19] had three cases out of 110 prostatectomies. Goodfellow also reports three cases. George W. Hawley[21] claims that it demands closer clinical observation, and that it is distinctly operable before metastases have taken place, the danger of delay in operating in doubtful cases is therefore evident. The symptoms he gives are pain, tenderness, and cachexia, with hard nodes in either a hypertrophied or a contracted prostate, and with or without urinary obstructions. Deposits may be found in the urethro-vesical trigone, seminal vesicles, pelvic lmyph glands, and diffuse metastases in the trunk bones. The blood shows a myelocytosis and a quantitative alteration of the erythrocytes. Every surgeon should be on the alert for the above symptoms, lest a grave mistake be made in the operation or prognosis.

Geo. Goodfellow (*Journal American Medical Association*, November 12, 1904) reports three cases of syphilitic prostates. The symptoms were similar to ordinary hypertrophy, but ceased after the use of potassium iodide. One was operated on and was found to contain a grumous material. He believes these are more frequent than is supposed, and urges greater care in the diagnosis.

The *prognosis* depends upon many conditions, as the age and the vitality of the patient, the duration and degree of the bladder and kidney symptoms. The shape and size of the prostate and the operation indicated. (See statistics below as to mortality.) Most authorities believe in the large number of cases that impotence will result. Horwitz says it is caused by severing the nerves to the prostate and breaking an important and complicated nervous mechanism, and is not due solely to the injury to the ejaculatory ducts; consequently it nearly always follows prostatectomy. Goodfellow, however, reports cases without impotence, as do other surgeons who advocate the methods of preserving the ejaculatory ducts. In careful operations permanent lack of control of the urinary function is rare, although Proust (in His Manual on Prostatectomy for Hypertrophied Prostate, Paris, 1904) admits that patients have some difficulty in retaining the urine after the perineal operation. Contrary to former views of Thompson, Guyon, and many others, the bladder is now known to regain its contractile power after the obstruction is removed. Sir Henry Thompson, in a recent personal

letter to Mr. Freyer, admits this change of his opinion (Walker, *The Practitioner,* August, 1904). Weiner reports one stricture and Goodfellow three, but thinks perhaps one or two may be due to malignant disease. It remains to be seen if the removal of urethra will be eventually followed by stricture. In all cases, however, it is better after five to seven days to pass good size sounds once a week as a precautionary measure, for apparently good results have followed their use. Mr. Freyer, however, does not now pass the catheter as after his former operations, because he believes there is no danger of a stricture. (*The Practitioner,* September, 1904.)

Time and Choice of Operation.—We have now reached the difficult problem, and will consider the opinions of some of the leading surgeons. All agree that operative measures should be adopted before the "breakdown in catheter life," but should they ever be started with a catheter? G. Frank Lydston[21] of Chicago says the earlier the operation the fewer are the obstacles encountered, and that in the beginning, early enucleation of adenomatous growths may be removed with ease, but, if allowed to progress, undergo changes which make the operation very difficult. He thinks the mortality from operations under favorable circumstances should not be higher than interval operations for appendicitis.

Horwitz[22] of Philadelphia claims the danger begins when the patient commences the daily use of the catheter, and that a Bottini or a prostatectomy performed as soon as the symptoms begin, has such a low mortality that it offers a better chance of health, comfort and a prolonged life than the use of the catheter.

Watson[1] of Boston does not consider the use of the catheter advisable. If the patient has been using a catheter and has serious kidney and bladder complications that counter indicate a radical operation, he advises suprapubic drainage, with attention to the general health, and if there is a marked improvement, an operation is indicated, otherwise the surgeon had better avoid a radical operation.

Hunter McGuire collected 107 suprapubic drainage operations, with but two deaths, and this relieves cystitis, pain, tenesmus, and improves the condition of the kidneys. Cabot[23] of Boston has shown that uremic symptoms disappeared after permanent drainage and pyelonephritis was much improved or cured. Deaver[2] says there are many patients who only have to pass the catheter once or twice in 24 hours who may have life prolonged and sometimes live in comfort, but that their "expectancy" can only be four or five years, as shown by Harrison and Lydston. Mr. Freyer has not formulated any rules as to when his operation should be used, and is very careful in selecting his patients. The concensus of opinion is that an early operation is the best. Catheterization may be used temporarily until the patient's condition permits an operation, or the next mildest method is permanent suprapubic drainage; an oblique incision down to the bladder, as advocated by McGuire, furnishes a very satisfactory fistula and is somewhat under control. Permanent catheters in the urethra are not advocated by the leading surgeons.

The choice of operation is dependent upon the conditions found, which demand some particular course, and no routine treatment for all cases can be advised, and, except in a few instances where the surgeons are so narrow-minded that they can see good in but one operation, the majority admit there are three valuable radical measures of treating prostatic hypertrophy—perineal prostatectomy, suprapubic prostatectomy, and the Bottini operation. Statistics show that all these are capable of furnishing good results when applied to the cases suitable for them.

The anesthetic required for each case must be considered in deciding upon the operative procedure, suprapubic drainage and the Bottini can be done with cocaine, and Murphy[24] says local and spinal anesthesia should be preferred in selected cases, or, better, epidural injection of one gram of a 1½ or 2 per cent solution of cocaine into the sacral canal through the hiatus sacralis, passing the needle 2½ inches up the bony canal. With this Murphy does a perineal prostatectomy. Parker Syms[26] now also uses spinal cocainization almost exclusively. Joseph Weiner[25] of New York advocates nitrous oxide gas when chloroform and ether are counterindicated, and claims brilliant results from its use and suprapubic prostatectomy. He claims there are very few counter indications.

Watson analyzed 2,627 collected cases to determine the relative danger, limitations, and results, and found the mortality of the Bottini and the perineal prostatectomy practically the same—6.3 and 6.2 per cent. Total suprapubic removals, 11.3 per cent. Selected operators gave better results. The mortality from uremia is about the same in all the operative procedures, except slightly lower in the Bottini, and is therefore more useful in deciding if an operation is advisable than upon the method. The perineal operation gave a higher mortality from shock and pulmonary complications and uremia than the Bottini, but not quite as high as the mortality from the suprapubic. Sepsis was most frequent in the Bottini and least frequent in the suprapubic operations—one-half less than in the perineal, in spite of the claim of certain authorities that the drainage in the suprapubic operation is so poor.

Disadvantages of the Bottini are inefficient drainage of the bladder and liability of retention; secondary hemorrhage, epididymitis, orchitis, repetition of operation may be necessary, small percentage of cures, inability to see the steps of the operation. The disadvantages of the perineal operations are a greater danger from pulmonary complications and liability to injury of the rectum and membranous urethra, with rectovesical fistula, or incontinence of urine. The suprapubic route has liability to shock and pulmonary complications, and a high mortality. Combined operations show high mortality, pulmonary complications, shock, and unnecessary opening.

Advantages of the Bottini operation are low mortality, slight pulmonary complications and shock, absence of general anesthesia, low mortality from uremia, short confinement, and no wound to heal. The perineal route has low mortality, complete result, and open to visual dissection.

The suprapubic has less danger of injury to the rectum and membranous urethra. Room for removing larger masses and a shorter time required. Combined operation gives greater control of gland and better drainage, but a mortality too high to consider it.

No surgeon should have his method of procedure outlined before the examination of the patient, and then all the conditions found should be carefully considered and the operation selected that will probably have the least interference by complications. He should also bear in mind the advantages and dangers given above, and if the patient cannot bear a general anesthetic and the kidneys are diseased and danger of shock is great, the gland being suitable, the Bottini is the safest method, while if the prostate has a large intravesicular adenomatous growth, the suprapubic route is more advisable. For hard prostates of small size and very adherent, Mr. Freyer himself says his operation is not suitable,

while Murphy, Deaver, and Goodfellow, and many others advise the perineal operation for these and a large number of cases intermediate between them and the large adenomatous prostates, especially where the enlargement is along the urethra or back toward the rectum. The mortality is now one-half what it was fifteen years ago, and even less by selected surgeons.

The following statistics are from a number of representative men on the various methods of procedure, and may be taken as about the mortality to expect:

Bottini Operation.—Horwitz, 95 cases, 3 deaths; Freudenberg, 25, 0; Young, 41, 3; Bangs, 34, 3. Total, 195 cases, 9 deaths. Mortality, 4½ per cent.

Perineal Operations.—Watson, 14 cases, 2 deaths; Goodfellow, 72, 2; Albarran, 59, 2; Proust, 30, 0; Pauchet, 20, 1; Rafin, 20, 1; Murphy, 51, 1; Horwitz, 38, 6. Total, 304 cases, 15 deaths. Mortality, 5 per cent.

Suprapubic Operations.—Freyer, 107 cases, 10 deaths; Moynihan, 12, 1; Weiner, 8, 0; Mayo Robson, 12, 0; Horwitz, 11, 2; Barling, 10, 3. Total, 160 cases, 16 deaths. Mortality, 10 per cent.

Although the larger number (2,627) collected by Watson showed a higher mortality, selected operators show a lower mortality, as Horwitz and Freudenberg report 120 cases, Bottini's method, with only three deaths. Murphy, Goodfellow and Proust report 153 perineal prostatectomies, with but three deaths. Less than 2 per cent mortality.

A mere glance at these statistics is all that is necessary to refute the claims made in the August *Practitioner* by Mr. Walker, who, in a glowing tribute to Mr. Freyer, says that the question of perineal, as opposed to the suprapubic prostatectomy, does not appear to be ripe for discussion at the present time, as the advocates of the perineal route have a showing too poor for consideration. Mr. Walker's Bibliography contains references only to the works of English surgeons, therefore it is with a feeling of distinct satisfaction that he has referred to the reports of Murphy, Goodfellow, and many others, who have operated on a sufficiently large number of consecutive cases, with most gratifying results, and with a much lower mortality than is shown by Mr. Walker in his 83 collected cases with 10 deaths (Freyer's operations) to show that the perineal operations are worthy of careful attention, especially in small adherent fibrous prostates. Of course, every one admits that the suprapubic operation is the one of choice where the intravesicular growth is large and adenomatous, with more or less mobility, but to fail to find other cases suitable for the perineal route, in the light of the present literature and experience, seems astounding.

If the bladder is badly infected and the patient too weak for operation, suprapubic drainage should be used, and by careful diet and hygiene the general health improved and the bladder and kidneys flushed with copious draughts of water and urinary antiseptics administered in suitable doses; if this does not bring about marked improvement, a radical operation will be disappointing. No rules can be laid down, because no cases are just alike; therefore, no routine treatment can possibly be advised, but must always be determined by the conditions to be combated.

The Technique of Operations.—This will be only given most briefly, omitting many details.

Suprapubic.—Mr. Freyer[19] says the bladder should be irrigated and then inflated, and the catheter left in the urethra—other operators inject not more than four ounces of fluid into the bladder. Incision is made through the space of Retzius and the bladder wall entered. The "transverse and longitudinal" incision of Rafin, Küstner, and others, and enthusiastically advocated by Stimson in the August number of the *Annals of Surgery*, may prove desirable in a certain number of these cases. It may or may not be sewn to the abdominal wall to steady the prostate, prevent stripping of the bladder from adjacent tissues, and subsequent urinary infiltration (Deaver). Mr. Freyer uses the sharpened finger nail to score through the mucous membrane over the most prominent part, and then the true capsule is reached, as the sheath does not cover this part of the prostate. The enucleating finger must keep in close contact with the true capsule, and in the space between it and the sheath from which the gland is enucleated. During the enucleation a gloved hand, with two fingers in the rectum and the thumb on the perineum, presses the prostate up into the bladder. The catheter can be felt in the urethra, from which this half of the gland is shelled, if possible. Otherwise, remove the urethra with it. Mr. Walker[27] has shown that the part above the veru montanum is more closely attached than the part below, and, consequently, is more frequently torn away, but apparently with equally good results. The other lobe is enucleated in the same manner, and they are pushed into the bladder and removed with forceps. Sometimes the lobes come away separately, and then Mr. Freyer claims the urethra and ejaculatory ducts are preserved. Many others claim they are torn away, and Mr. Moynihan[28] makes no effort to preserve them. Hemorrhage is checked by hot irrigating solutions, to be used not more than two or three minutes.[29] The edges of the cavity should be pressed together to obliterate the space from which the prostate was removed, and this rapidly fills in. A drainage tube (⅞ inch) is used in the wound for two days, and a small amount of gauze is placed in the angle of the opening to prevent infiltration of the pre-vesicle space. The wound is sutured around the tube. The bladder is irrigated through it once daily until removed, then through the fistula until it closes. A catheter is not left in the urethra, nor does Mr. Freyer pass a catheter subsequently to prevent a stricture. All authorities agree that the patient should be up at the earliest possible time, in order to prevent pulmonary complications.

Perineal Operation.—The exaggerated lithotomy position is advised by the majority. There are many minor variations in the details of the technique of the different surgeons who advocate this method. If only a small amount of room is needed, one may use, as does Goodfellow[30] and Deaver, the median perineal incision, or if more space is desired, the incision may be enlarged by making an oblique cut on each side of the rectum, giving the inverted Y incision, as advocated by Murphy and other good authorities. Deaver cuts down on a sound which is used to depress the prostate, or the finger may be passed into the bladder through the urethral incision for the same purpose, as advocated by Albarran. Murphy makes a transverse incision in the sheath of the prostate, and in this way he thinks the danger to the rectum is lessened. Young and others advise incision of the sheath over the lateral masses parallel to the urethra, to preserve it and the ejaculatory ducts. Murphy begins the separation at the base of the prostate, where the attachment is less firm, and uses hooks of his own design for drawing down the lobes of the prostate. After its removal he cuts away any remains of pouches of the prostatic urethra, and sutures the urethra, except at the drainage tubes. Watson[1] opens the prostatic urethra two-thirds its length, and enucleates with the finger along the inner lateral wall of the urethra,

and he, Goodfellow, and many others do not sew up the urethra or cut away the pouches, as they claim it increases the hemorrhage and delays the operation unnecessarily. Goodfellow does not drain the wound with a tube, gauze, or anything, but Murphy, Watson and Deaver and the majority of surgeons drain it with a rubber tube and pack gauze around it. Plenty of gauze is used over the wound and a T bandage applied. Deaver connects the perineal tube to a bottle hanging by the bed. The bladder is irrigated daily and the tube left in as long as the urine contains pus. Pyle and Nicoll do not open the urethra. Proust[31] (1901) exposed the posterior surface of the prostate and dissected out the ejaculatory ducts and blood vessels. Albarran's method differs a little. He does not ligate the ducts, and begins a separation at the outer side and cuts off the anterior part, when free, to give more ready access to the posterior half. Murphy passes the finger into the rectum at the beginning to avoid injury to it, while he cuts the central bridge of tissue in the perineum close to the rectal wall, as an anterior incision would cause severe hemorrhage if it involved the corpus spongiosum. Cutting this central tendon is the keynote to obtain plenty of room by this route. The roof of the urethra should always be retained, when possible, for it has been shown by Inginni[32] that the rest of the urethra will be regenerated from this.

Bottini.—Horwitz is an ardent advocate of this method in selected cases, and gives the names of Bottini, Freudenberg, Meyer, Casper, König, Guiteras, Young and many other eminent men whose experiences corroborate his own. Lydston and Weiner advise against cystostocopy, while Horwitz, Young, and Watson advocate it. Of course, if there is an obstruction to its easy passage, it should never be used, but in such a case the Bottini method would not be the one of choice. The finger in the rectum is essential to prevent injuring the rectal wall and assists in determining the exact location of the blade. The electric currents should always be thoroughly under control. The incisions are to be made in selected places, according to the shape of the prostate, as taught by Freudenberg. The size of the enlargement regulates the blade to be used (Young), and the length of the incision to be made. These should always be made slowly and with the bladder distended with fluid. Recently, in Israel's clinic, in Berlin, during a Bottini operation according to the usual technique, the bladder ruptured with the sound of an explosion. Experiments made since the accident show that the sudden formation of steam was the cause. No method to obviate this has been devised, consequently it is a point in favor of prostatectomy.

Conclusions.—(1) Literature on prostatic surgery has been very confusing, owing to the large number of methods of operation advocated by prominent surgeons.

(2) Suprapubic drainage of the bladder is advised in those cases too weak to withstand an operation; if improvement follows this procedure, then a radical operation is indicated.

(3) There are three radical methods that are without doubt the most valuable; suprapubic prostatectomy, perineal prostatectomy, and the Bottini operation, and each of these has a definite place in prostatic surgery.

(4) The relative advantages and dangers of each method should be well known, as the pathology and conditions are so varied that no routine treatment for all cases can be advisable.

(5) All patients should be operated on before the breakdown in catheter life, and the earlier the operation the fewer will be the complications encountered.

(6) The suprapubic route is indicated when there is a large intravesicular, mobile, adenomatous growth, with general health and bladder and kidneys in a satisfactory condition.

(7) The perineal operation is more desirable for small, dense, fibrous prostates firmly attached, and those where the growth is largely along the urethra or back toward the rectum.

(8) The Bottini is indicated in those cases where prostatectomy is refused and in selected cases, where the general health and kidneys counterindicate more radical measures. Of course, it is never to be used for a large, rapidly growing hypertrophy.

(9) In the suprapubic operations avoid hemorrhage by keeping carefully between the capsule and the sheath. In the perineal operations carefully cut the central tendon of the perineum close to the rectum, but with the finger in it to prevent injury. Avoid laceration of membranous urethra, as incontinence of urine will follow.

(10) Marked improvement results in the large majority of cases where the operation has been properly selected and carefully performed.

Is Symphyseotomy a Surgically Incorrect Procedure?—Zweifel very vigorously opposes the dicta of Gigli, who has cast many aspersions on the classical operation of symphyseotomy, and offers as a satisfactory substitute his own operation of lateral section of the ramus with the wire saw, or hebotomy as it has been called by van der Velde. Properly done, Zweifel says that symphyseotomy has no disadvantages that are not shared in equal measure by Gigli's operation and the older method has the advantage that in subsequent labors the scar tissue usually stretches enough to permit of nonoperative delivery.—*Zentralblatt für Gynäkologie.*

THE DIAGNOSIS OF RENAL AND URETERAL CALCULI.*

By H. A. FOWLER, M.D.,
WASHINGTON, D.C.

THE formation of urinary calculi depends upon the defective elimination of certain products occurring normally in the urine, chief among which are uric acid, calcium oxalate, and the phosphates. Normally, these are eliminated without attracting any more attention than does creatinin, which is present in the urine in about the same amount as uric acid. But under certain abnormal conditions, these salts assume the greatest clinical and pathological significance.

Urinary calculous disease must be a very ancient affection. It must be as old as the human race, unless, perchance, the method of elimination of these substances in the urine was at one time better adapted to the requirements of the organism, or unless hypertrophy of the prostate gland is a recently acquired pathological condition. Certain it is that reference to this disease is as old as medical literature.

It is very interesting to trace the development of our knowledge of the formation of urinary calculi as reflected in the various theories which have been advanced since the earliest times. Probably no one subject in medicine has such an extensive literature, and no single problem has elicited the thought of so many men in the attempt at its solution.

Why do stones form in one person and not in another? What conditions are necessary for their development? How can we prevent their formation or recurrence? These questions are still very puzzling, and we must admit that an adequate explanation cannot be given. But we know a great deal more about the underlying causes of stone formation than we did a few years ago. The first really scientific study of the subject was made by Rainey, 1858. The work of Ord, of Roberts, and, more recently, of Ebstein, is exceedingly interesting and valuable, and raises the hope that eventually we may be able to take intelligent measures for the prevention of calculous disease. I should like very much to give a résumé of the work of these investigators, but we must not allow our enthusiasm to lead us into this by-path, although the temptation is strong and the vista attractive.

We may, however, stop long enough to answer one question: "What is the present conception in regard to the formation of a urinary calculus?" Very briefly we may say that the following conditions are necessary: (1) The presence in the urine of the inorganic salts—the stone-forming materials, "steinbildners." (2) The presence in the urinary tract of a catarrhal or inflammatory condition which furnishes the *organic* material—the framework, "gerüst." (3) Changes in the urinary passages which prevent the escape of the nucleus, thus permitting its further growth.

The most essential factor is the presence of the organic material without which no stone will develop.

In the second Hunterian lecture for 1898, Morris, speaking of renal calculous disorders, said: "If I put them in the very forefront of surgical affections of the kidney, I do so for the following reasons: (1) They are the most frequent and the most painful of the surgical diseases of the kidney; (2) few operations in surgery are so successful as nephrolithotomy. It gives absolute cure, saving the kidney from progressive destruction, and the patient from what at any time may be an imminent danger of life; (3) no disease gives rise to such a variety of morbid changes in the kidney as calculus when allowed to progress without surgical interference. (4) renal calculus, whilst slowly destroying the kidney, often physically disables its victim by its unrelenting irritation and its unyielding resistance to every form of medical and dietetic treatment."

The frequency of this affection seems to depend largely on the care which we take in making the diagnosis in many cases of obscure lumbar pain and "nephralgia." Only a few days since, in the course of conversation, a man told me that he had suffered with attacks of very severe pain in the back and loins which required morphine and incapacitated him for work a greater part of the time. He was treated symptomatically and expectantly, no diagnosis, apparently, having been made. One night, after an unusually severe attack of pain radiating from the loins downward to the urethra, he made his own diagnosis by passing per urethram a small, rough, jagged calculus, about the size of a pea. His "stomach trouble" disappeared with this attack, as did the pains in his back and loins.

There is probably no disease except acute tetanus and trifacial neuralgia which causes such intense suffering. On the other hand, a patient may carry about an enormous stone in the kidney for years without any symptoms indicating its presence. But just these cases are the most dangerous, because they lead, inevitably, to a slowly progressive destruction of the kidney. As, in appendicitis, we never know what cases are going to perforate and set up a general peritonitis, so, in calculus of the kidney, we cannot say what cases, if allowed to go on, will result in calculous anuria, pyonephrosis, abscess and fistulæ, not to mention other distressing complications. After an acute attack, presenting all the classical symptoms of stone in the kidney, we may be lulled into a false sense of security by a persistent freedom from further attacks, and we may congratulate ourselves and our patient that matters terminated so happily. But we are very likely, sooner or later, to be disenchanted, and it may be years after that we are called again to find the kidney entirely destroyed and transformed into a pus sac, and the other kidney the seat of calculous disease. Unfortunately, such experiences have not been uncommon.

It is only within the past few years that we have been able to offer these unfortunate sufferers very much encouragement. About all that could be done was to relieve the pain and hope that the stone might pass the ureter. Happily, this is all changed. With the rapid advances in renal surgery in the past few years, and with the brilliant success which has attended the operation for the relief of renal and ureteral calculi, our interest in the whole subject has been wonderfully revived.

The diagnostician tried to keep pace with the technician, but he was left far in the rear, and is only recently coming into view again with the whole host of new methods and tests. Indeed, the work from the point of view of diagnosis in renal affections in the very last years has been revolutionary. New methods are being introduced at such a rate that one can scarcely keep abreast of the times. Other tests from which much was expected have already been laid aside. Practical results have, however, already been attained, the importance of which we cannot afford to overlook. Kümmel, for instance, has recently reported that since the introduction of the more accurate means of diagnosis, his mortality in kidney operations has been reduced from 28 per cent. in 168 cases, to 4.8 per cent. in 98

* Read before the Medical and Surgical Society of Washington, D. C., March 28, 1904.

cases. Such results as these are striking and mark a new era in kidney surgery.

One of the most important aids in making a diagnosis of this condition is a good history. Next to a good history, I should place, in the order of their importance, physical examination, urine examination, cystoscopy, radiography, ureteral catheterization, and exploratory incision.

The taking of a full, complete, and satisfactory history is, unfortunately, a rare accomplishment. We are very apt to slide over this important detail. We are in too much of a hurry to get at our patient. This very haste often costs us valuable information. A patient never remembers to tell us all his symptoms, and there are many points sometimes of the greatest significance, which to the patient seem trivial and not worth mentioning. This may seem a very trite matter, but, in my experience, it is a point of the greatest importance, and the one most often overlooked or not attended to with the care and detail it merits. It not infrequently happens that after the diagnosis has been made and confirmed, if we are conscientious, we go back and patch up our histories, adding points which were obtained after the history was hurriedly written—points which, if we had been more careful to inquire into at the first visit, would have made the diagnosis much easier.

Physical Examination.—Very rarely can one palpate stones in the kidney, but such cases have been reported, it having been possible to feel the stones grate on each other. Calculus of the lower end of the ureter is felt, not uncommonly, by rectal and vaginal palpation. Tenderness, on deep palpation over the kidney and along the course of the ureter is frequently present with stone and may be very suggestive in association with other signs. I have a patient now with stone in the kidney who has great tenderness over the kidney and along the ureter. He has had one large calculus removed from this kidney and has since passed a small stone.

Urine Examination.—The urine in these cases may contain organisms, or it may be free from infection. Thus, we may make two groups: (1) infected, and (2) non-infected. Those cases which have escaped infection have usually also escaped extensive destruction of the kidney. The examination of the urine in such a case may be absolutely negative, if made between attacks. I had recently a very instructive case of this kind. This patient, a young school teacher, came to me complaining of frequency of micturation. For the past ten years he had been passing his water at frequent intervals, day and night. He was very nervous and broken down from loss of sleep. He gave a history of "stomach colic" of long duration, to which, however, he attached very little importance, and I did not question him closely at this time. He had come East to St. Louis for treatment. The physician whom he consulted told him he had an enlargement of the prostate and would have to have an operation. While in St. Louis, he had another attack of his "colic" which required a hyperdermic of morphine. He was advised to go on to Baltimore for the operation. When I first saw him, July 18, 1903, the following note of his urine was made: "All three glasses cloudy; specific gravity, 1020; slightly acid; free pus cells and a few red blood cells." The next day the following note was made: "All three glasses clear; an occasional leucocyte seen." I was greatly surprised to find his urine clear and, microscopically, to be quite normal. This difference in the two examinations led to further questions about his attack of "stomach colic" in St. Louis, and I began to patch up my history. I obtained a history of renal colic which began when he was ten years old, had been repeated at intervals ever since, and at times had been associated with bloody urine. Thus were the findings, as given above, explained. I had caught the patient just as the attack which he had in St. Louis was clearing up, the urine still showing a small amount of pus and blood. One day later the urine was quite clear. In this patient a calculus in the lower ureter was diagnosed, and I removed it later by the extraperitoneal iliac route.

In one case of vesical calculus upon which I operated, the patient complained of pain in the back, which incapacitated him for his work as a tailor. The urine examination showed nothing abnormal. Cystoscopic examination disclosed eight small stones lying behind the prostate gland which was only slightly hypertrophied. There was no cystitis; the stones were clean, pure white, giving a beautiful cystoscopic picture.

When the urine contains a large amount of pus or blood, or both, we have to exclude tuberculosis by a search for the tubercle bacilli. For this purpose a smear should be made from a centrifugalized specimen taken from the third glass. The last urine is less likely to be contaminated by the smegma bacilli. In all cases of pyuria and hæmaturia, this examination should be made, even though the history strongly suggests calculus. In a case which Dr. Young has reported, the diagnosis of probable stone in the kidney and ureter was made and a nephro-ureterectomy was performed. I afterward found the tubercle bacilli in the urine passed just before operation. In this case the diagnosis of stone seemed so clear that the routine examination for the tubercle bacilli was overlooked.

Cystoscopic Examination.—In all cases of suspected calculi of the kidney or ureter, unless there are special contraindications, cystoscopy should be performed. It is very helpful, indeed well nigh indispensable. I know of no objection to the use of the cystoscope in these cases. The technic is simple, and it is not a trying ordeal for the patient, as is too often supposed. I might give a number of examples illustrating the value of the cystoscope in this class of cases, but I will refer briefly to only two.

A young man came to Dr. Young with a discharging sinus situated over the tip of the twelfth rib. This he had had for a number of years. An abscess had originally formed in this location, ruptured, and a sinus had persisted in spite of repeated efforts to close it. A probe could be introduced inward and upward a distance of seven cm. in the direction of the tip of the twelfth rib. There was no necrotic bone to be felt and no tenderness on pressure over the rib. The urine examination was negative; there were no symptoms referable to the kidney. Cystoscopy was performed, more as a routine procedure than for any other reason. A remarkable condition of affairs was at once disclosed. The left half of the trigone was markedly atrophied, flat, and the ureteral orifice scarcely visible. The left kidney was not functionating. The right side of the trigone was hypertrophied, the orifice large and gaping and spurts of urine could be seen ejected from it at intervals more frequent than normal. Here was the explanation of the persistent sinus. The *x*-ray plate showed shadows in the left kidney. The operation later confirmed the diagnosis; the kidney was transformed into a small fibrous capsule completely filled with stones.

The second case was a young man with symptoms not unlike those of vesical calculus. His physician had explored his bladder with a Thomp-

son's searcher, with a negative result. The urine was normal. A plain Nitze cystoscope showed the bladder to be free from stone. The right side of the trigone was prominent; the ureteral papilla was distinctly larger than the left side. The left ureter was not seen to functionate. So great was the contrast in the two sides of the bladder that there seemed little doubt of an obstruction of the left ureter at a point above its vesical orifice. To confirm these suspicions and clear up the diagnosis definitely, I introduced a Caspers catheterizing cystoscope. The catheter engaged readily and passed into the ureter a distance of four cm., where it met an impassable obstruction. Further pressure on the catheter caused it to buckle into the bladder. This buckling of the catheter was demonstrated to the two visiting physicians present. The "probable diagnosis" made with the plain cystoscope was confirmed and the stricture definitely located. The *x*-ray plate showed a shadow distinctly at this point, and, about a month later, the stone was removed, thus leaving no doubt as to the diagnosis.

These two cases illustrate very well the value of the plain cystoscope in cases in which the urine examination is negative. The cystoscope gives us information on the following points: (1) Presence or absence of vesical involvement—calculus, tumor, etc.; (2) difference in two sides of the trigone, suggesting a lesion higher up, either calculous or tuberculous; (3) presence of ureteral calculus at its vesical orifice; (4) in cases of pyuria and hæmaturia, which kidney, if the disease is unilateral, harbors the foreign body.

Catheterization of the Ureters.—Reference has already been made to the use of the ureteral catheter in determining and locating strictures of the ureter due to stone. But it has a wider application. In certain cases, it is of the utmost importance to determine the work which a kidney, the seat of calculous disease, is doing. This becomes all-important when the operation of nephrectomy is to be considered. At the risk of tiring with case records, I wish to recall, very briefly, a case in point.

This patient, about forty years of age, was suffering constant pain in the right loin. His urine contained an abundance of pus, but no blood and no organisms. The plain cystoscope showed purulent urine escaping from one ureter, while from the other it seemed clear. Double ureteral catherization was performed. The urine thus collected separately, showed microscopically, pus in both specimens. There were shadows in both kidneys in the *x*-ray plate. Both specimens were examined carefully for the comparative determination of specific gravity, albumin, urea and the cryoscopic test. It was found that both kidneys were doing a fair amount of work. From one kidney, one large stone and thirty-three small ones were removed. After the wound had healed, double ureteral catheterization was again performed. A study of the specimens of urine this time showed that the kidney which had been operated on was doing better work than the other. From the second kidney one large stone and fourteen small ones were removed. This patient eventually made a good recovery, and now has two good kidneys. The ureter catheter in this case enabled us to judge, before the operation, the condition of each kidney, and indicated the operation to be selected. In not a few cases of bilateral renal calculus, a nephrectomy has removed the only kidney which was working, and the patient paid for the mistake with his life.

Radiography.—There is considerable difference of opinion among surgeons as to the value of *x*-ray examination to determine the presence or absence of a calculus in the kidney and ureter. Morris, in his book on the kidney, is very conservative in his attitude. He quotes cases in which a positive diagnosis had been made by radiographs, but at the operation no calculi were found. Leonard, of Philadelphia, who is the greatest authority in this country, on the other hand, maintains that a positive diagnosis can be made in every case, and goes so far as to say that a negative finding is of as much value as a positive result; in other words, that, in case the radiograph is negative, calculus can be excluded. Not many are willing to take this advanced position, because there are few or none who have had the success which Leonard has had. But no one doubts the value of the *x*-rays in these cases. In the experience of the majority of surgeons, greater dependence is to be placed on positive results. In a considerable number of cases, I do not recall one, in which the *x*-ray examination was positive, that operation failed to confirm the diagnosis. In one case in which the report of such an examination was negative, at operation a very large calculus, occupying the entire kidney, was found. In this case, the kidney was tucked up under the ribs, and was held securely in place by very dense adhesions. The capsule was greatly thickened and fitted accurately over the stone. Doubtless, these conditions rendered its differentiation by the rays very difficult or even impossible.

The value of the *x*-ray examination depends largely on (1) the weight of the patient—thin patients are much more satisfactory, and (2) the experience and skill of the examiner. It requires a great deal of experience to secure a sharp, clear differentiation of the kidney from the surrounding tissues of such clearness as to detect a calculus which might be present. If a positive diagnosis is made by one who has had considerable experience in such work, we may feel pretty certain that a stone is present. But, in the case of a negative report, we cannot feel so certain in the presence of other positive indications.

Exploratory Incision.—There will always be a certain number of cases in which it is impossible to make a definite diagnosis, although the number of such cases is greatly diminished by the more accurate means of examination at our disposal. For this class of cases we reserve exploratory incision. Cutting down on the kidney for purposes of clearing up the diagnosis in obscure cases, and the relief of the conditions found, is not only a justifiable procedure, but it has led to the discovery and relief of conditions entirely unsuspected and unknown—conditions which caused untold misery and suffering. The exploratory incision may be a "negative one," so far as the presence of a calculus is concerned, but it allows us to correct any abnormal condition which may be present and give the patient relief. And for what better reason can any operation be undertaken?

In conclusion, I wish to emphasize the importance of early diagnosis in these cases of renal and ureteral calculi, for the following reasons:

(1) By early surgical interference, we can save the kidney and give the patient relief from a disease which, "though swift and fatal in anuria, torturing in colic, and slowly, grimly progressive in suppuration, also presents possible vistas of years of comparative health and comfort, a delusive prospect with which the timorous sufferer would fain brace his refusal of the knife."

(2) The operation of nephrolithotomy offers a perfect cure. No operation in surgery is attended with more brilliant success. The mortality of this operation is about the same as that of lithotrity,

while the dangers of nephrotomy and nephrectomy are many times greater.

(3) By an early diagnosis and operation, we avoid alarming and distressing complications and a final resort to these more serious operations.

The Cumberland.

GROWTH OF BONE IN THE TONSIL.*

By WILLIAM WESLEY CARTER, A.M., M.D.,

New York.

Assistant [illegible]

My interest in the growth of bone in the tonsil was aroused by the recent appearance of several excellent papers upon this subject, notably those of Newcomb, Lubarsch, Pollak and Ruckert. The condition is not considered in the various text-books which I have consulted. Cases in which the styloid process reaches down to, and is included in, the tonsil have been reported by Newcomb, Richards, Stirling, and others; these men have recognized the extrinsic origin of the bone, and could trace it to the base of the skull.

Bone originating in the tonsil itself (with which this paper has to deal) probably occurs more frequently, and certainly has been more exhaustively dealt with in the literature. This condition is not of great importance to the clinician, as no special symptoms seem to result from it, and it has always been discovered by accident. To the pathologist, however, it is a matter of absorbing interest, and his ingenuity has been taxed to the utmost to account for it. Two theories have been advanced: (1) That it is due to developmental changes in the remains of the second branchial arch; and (2) that it is produced by metaplastic changes in the connective tissue of the organ. Each of these theories has about an equal number of adherents.

The following case came under my observation in Dr. Knight's clinic at the Manhattan Eye, Ear and Throat Hospital:

Margaret H., age 22, a domestic of good family history, applied for treatment on April 7 because of repeated attacks of tonsillitis. In other respects she was perfectly healthy.

During the last ten years she has had as many as a dozen peritonsillar abscesses, most of which were on the left side. She says that even between attacks her throat never felt well, each swallow of solid food being attended by a certain amount of discomfort, referable to the tonsillar region, but to neither side in particular. Her last abscess had occurred on the left side about a month before I saw her.

Examination showed no signs of acute inflammation. The tonsils appeared as dense fibrous masses slightly larger than normal and firmly adherent to the pillars. The right mass was removed with the tonsil punch without unusual incident. When, however, the left was approached, I discovered that it contained a solid mass of such a shape that it could not easily be included in the grasp of the instrument. When I placed a probe against the tonsil I could easily see that it was freely movable and not attached to the bony skeleton.

After cocainizing the throat, I engaged a tenaculum in the upper extremity of the mass, and, lifting it from its bed, dissected it out from above downwards with a pair of long scissors curved on the flat. The specimen was about ¾ inch in length, ½ inch in width and ¼ inch in thickness. In gross appearance it resembled fibroid tonsillar tissue, and in its center could be felt a solid mass reaching almost from one end to the other.

* Read before the Section on Laryngology and Rhinology of the New York Academy of Medicine.

Dr. Wright, who examined the specimen, reported as follows:

Microscopical examination of a section made through the entire specimen shows it to be made up largely of fibrous and bony tissue, with a very small amount of lymphoid tissue in it. In the stroma of the organ a large number of areas of hyaline cartilage are observed, and some of these are plainly being transformed into well organized bone containing Howship's lacunæ and lined with osteoblasts and osteoclasts. There are some fat cells associated with the areas of bone formation. In some areas the bone is being formed directly from fibrous tissue, which at that spot has become as dense as ordinary periosteum; while in others, the transitional stages from fibrous tissue through cartilage to bone can be observed.

We have here, therefore, plain evidence of the active formation of both bone and cartilage from the stroma of an adult tonsil, and Dr. Wright thinks it problematical as to whether or not the process could have begun in embryonal life.

Newcomb infers that this condition is much more frequent than is generally supposed; for he has frequently removed tonsils which on examination showed compact particles the nature of which he did not investigate with the microscope, and which he believes were either cartilage or bone.

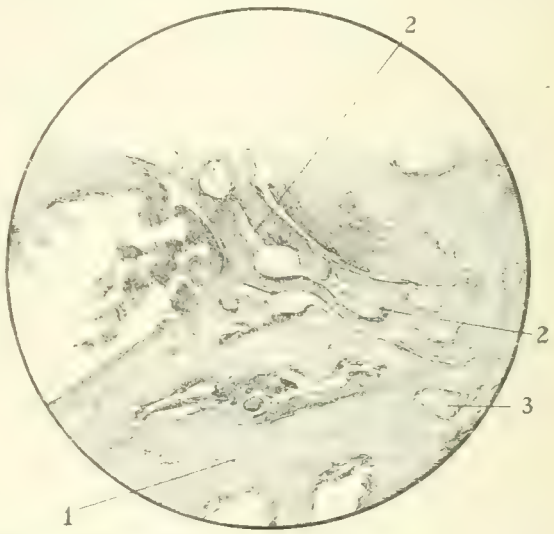

Fig. 1.—1, Fibrous tissue becoming changed into cartilage; 2, 2, bone containing lacunæ [illegible]

Reitmann, who examined three embryos and fifty tonsils, found cartilage in 17, or 34 per cent. The cartilage was hyaline and embryonal in its characteristics, it was surrounded by fibrous tissue and in some instances was being transformed into bone. In one embryo he thought it might have been an offshoot from the branchial arch. Walsham, Wingrave, His, Orth, and Deichert, who have recorded cases showing this condition, believe that the bone originates in the vestigial rests. Walsham found bone twice in thirty-four autopsies and Wingrave found cartilage three times in examination of two hundred tonsils.

Ruckert has just reported in Virchow's Archives three cases which came under his observation. The first was a woman who died from carcinoma. He found three or four deposits in one of her tonsils. The bone showed a lamellar structure, contained Haversian canals and small lacunæ filled with fat, but no osteoblasts. In the periphery were small cartilaginous deposits, and he could trace successively from cartilage containing calcareous deposits to bone. There were no signs of active inflammation.

The second case was in a man who died from

pulmonary phthisis. Both tonsils were inflammatorily enlarged—the superficial portion was spongy and the deeper of bony hardness. The vessels were distended and some blood had escaped. There were no tubercular changes. One single moderately large bone deposit was seen. The bone was well developed and was surrounded by cartilage, which merged into connective tissue. It contained medullary spaces and some osteoblasts.

The third case was in a man of forty years, who died of pneumonia. The tonsil was not enlarged, but contained near the lymphoid structure three large bony deposits and two smaller deposits near the muscular structure. Close to the periphery there was a deposit of cartilage which merged into the connective tissue. He regarded this as a case where both bone and cartilage appeared in an otherwise normal tonsil. Ruckert concludes that the bone is developed from the second branchial arch.

Among those who believe that the bone arises from fibrous tissue are Virchow and Kanthack. Nösske found bone and cartilage in the stroma of the organ, and transition pictures between it and the surrounding connective tissue, he believed that it was due to inflammation, retrogressive changes and a local predisposition to the formation of bone.

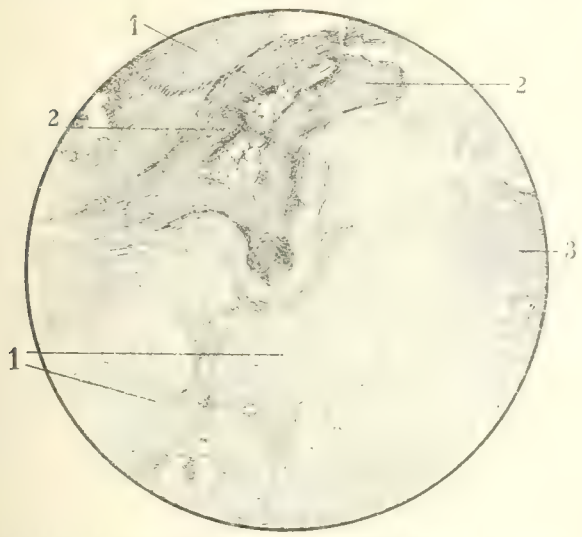

Fig. 2.—1, 1, Cartilage; 2, 2, bone; [illegible] tissue.

Toepfer and Rosenberg described a case in which they found multiple cartilaginous foci in the connective tissue of the organ, but never in the lymphoid structure; there were transition stages in the change from connective tissue to cartilage and in some sections to bone.

In a recent issue of Virchow's *Archives*, Lubarsch, who examined 587 bodies, quotes Pollak, who examined 275 bodies. He concludes (1) that bone frequently occurs in the lymph nodes of tubercular subjects; (2) that bone arises from a metaplasia of connective tissue around tubercular, cheesy masses, its formation being facilitated by the deposit of calcareous salts; (3) that cartilage and bone are derived partly from deposits during fetal life and partly from metaplastic changes in inflamed tissue. There certainly could be no connection between the deposit of calcareous salts in and around tubercular foci, and the active bone and cartilage formation as shown in my case.

In considering the origin of the bone, it is well to remember the mode of development of the tonsil. According to Heisler, in the third month of intrauterine life the lateral wall of the pharynx pouches out to form a little fossa between the second and third branchial arches; this fossa is lined with stratified, squamous epithelium, continuous with that of the pharyngeal cavity. At the bottom of this fo[illegible] little buds of epithelium proceed into the subjacent connective tissue; subsequently they become hollowed out and form the lacunæ of the fully developed organ. Leucocytes, wandering from the adjacent blood vessels into the connective tissue surrounding these buds, contribute the lymphoid element. The organ therefore appears between the second and third branchial arches, and the remains of the arches form the anterior and posterior palatine arches. From a study of my own case, and of the cases as reported by others, I am inclined to believe that the bone originates from metaplastic cha[illegible] the connective tissue, and not from the branchial arch, for the following reasons:

1. At the time that the tonsil develops the branchial arch has disappeared.

2. If the bone came from the arch, it should be uniformly distributed through the organ, and not confined, as it usually is, to the connective tissue.

3. The natural sequence of development of osteomata is from connective tissue, through cartila[illegible] to bone. This process is clearly shown in the specimen taken from my case.

4. Analogy with other organs shows that cartilage and bone are frequently found in the connective tissue framework of such glands as the parotid, the mammary gland and the testis, when these have been subject to chronic inflammation.

But since bone does not develop in every tonsil that has been subject to proliferative connective tissue changes, we must assume when it does occur some local predisposing tendency to its formation.

REPORT OF THREE CASES OF INTESTINAL ANASTOMOSIS BY THE CONNELL SUTURE.*

By H. H. SINCLAIR, M.B., M.D., C.M.,
WALKE[illegible]

Case I.—On May 17th I was called to the country by Dr. L. Sinclair to operate upon Mrs. T., a feeble old lady 65 years of age, who had been suffering for thirty-six hours from a strangulated inguinal hernia, which had resisted all attempts at reduction under anesthesia. She had had the hernia for thirty-five years, during which period it had become strangulated several times but had always previously been reduced. I found her in a state of collapse and vomiting almost continuously a brown fluid, fecal in odor.

Under chloroform I made an incision and opened the sac and came upon a loop of intestine black in color and tightly constricted. Hot water was applied for twenty minutes, but as the shimmer did not return, I made a resection, going well out on the bowel to get healthy tissue and good blood supply for

* Read at a meeting of the Bruce and Grey Counties Medical Association.

intestinal ends, cut a wedge-shaped section from the mesentery, and made an end-to-end anastomosis by the Connell suture. I then removed the sac and incarcerated omentum, finished with the radical operation for hernia according to the method of A. H. Ferguson. The bowels moved in thirty-six hours and, with the exception of a small abscess in the groin, which was opened ten days later, her recovery was uneventful. Five weeks later she was doing her share of the household duties, and is now free from digestive disturbances from which she suffered for thirty years.

In this case, as I was miles away from the hospital, had I not had a simple method of making an intestinal anastomosis without special instruments, I should have been compelled either to anchor the bowel and have a fecal fistula or to return the damaged bowel and trust to luck.

Case II.—May 27, I was called to see Wm. G., a young farmer 23 years of age, who had had four previous severe attacks of appendicitis. He had been seized with a sudden sharp pain in the right lower quadrant of the abdomen that afternoon, and when I saw him I found him retching, vomiting and suffering very severe pain. His pulse was 90, and he had a slight fever. I washed out the stomach and gave a high rectal injection of a large quantity of physiological salt solution. He passed feces and flatus and was more comfortable. I prohibited all food and water by mouth.

The next morning I found him more comfortable. Blood examination showed a leucocytosis of 10,500. I advised the man to enter the Bruce County Hospital, which he did. During that day I made repeated blood examinations and found a constantly increasing neutrophilia. The next morning, with Dr. W. C. Morrison of Paisley, I made a thorough examination of the patient, immersing him in a hot bath, and examining the abdomen, a method recommended by Benedict. We found nothing to warrant operation.

However, that night, from the patient's facial expression and the constantly increasing leucocytosis (now 18,000), I advised an operation, to which he consented. The following morning, assisted by Drs. L. Sinclair and Stalker, I made an incision through the right rectus and found an inflamed appendix, which I removed; but on further examination I found an old adhesive band extending from base of appendix across the cecum to the mesoceum about which a volvulus had occurred. At both points of constriction and at three points along the cecum the bowel was black and color failed to return after prolonged treatment with very hot water, therefore I resected the damaged portion, going well out into healthy territory to get a good blood supply (removing about eight inches of the ileum, the cecum, and a portion of the ascending colon), turned in the ends of the ileum and colon, and then made a lateral anastomosis between ileum and ascending colon, leaving about three inches of colon below the anastomosis to form a new cecum. The wound was closed without drainage.

The bowels moved in forty-eight hours, and the man's recovery was uninterrupted. He left the hospital in three weeks, and in five weeks was working around the farm, being able to help in the harvest fields. He is now in better health than he has been for several years.

After leaving hospital, patient gained seventeen pounds in seventeen days, and is relieved of all symptoms, being able to eat anything.

Case III.—J. W. F., farmer, single, aged 29 years, has suffered from gastric ulcer for three years, causing intense pain, anemia and great digestive disturbances, and which has resisted all approved medicinal measures, including a stay in hospital with special feeding. In his own words, life in his present condition was not worth living, and medicinal treatment by different men was of no benefit, hence he decided to undergo operation.

On November 21, assisted by Drs. Morrison and L. Sinclair, I operated at the Bruce County Hospital. Making an incision through the left rectus muscle, I came down on the stomach, which was adherent to the anterior abdominal wall. I found an ulcer which had eaten through all the coats of the stomach and was only prevented from spilling its contents by the motherly enfolding of the mesentery, which made it adhere to the abdominal wall. I made a purse-string suture around the ulcer, turned it in and applied Lembert sutures. I then made a retro-colic gastrojejunostomy by the Connell suture. The stomach was washed out every eight hours, and the patient has made an uninterrupted recovery.

My experiences with the Connell suture has thus been three cases with three recoveries. I was compelled to use it in the first case on account of lack of any special instruments. Since that time I have used it because I have confidence in it.

A query suggests itself: Has the lack of a simple method of doing an intestinal anastomosis been one of the causes of mortality in strangulated hernia and volvulus?

Recent Typhoid Epidemics and Their Lessons.—Dr. S. R. Towne, in the *Western Medical Review*, concludes from a study of recent epidemics: (1) That far oftener than we think typhoid is communicated by contact; (2) that it calls for the earnest attention of every medical man; (3) in all cases simulating typhoid, extreme cleanliness of patient and surroundings should be instituted and all excretions disinfected; (4) governments should aid in establishing an early diagnosis; (5) with diagnosis established, the sputa and all excreta should be disinfected and extreme care enforced in removing dust, excluding flies, in disinfecting waste food, utensils, clothing and the patient's person, particularly about the nates; (6) dairymen and other food producers should be subject to punishment for neglecting to report to health authorities all communicable diseases about their premises; (7) through the physician, the health authorities should enforce the methods needed to ensure good disinfection.

Diagnosis of Bronchial Asthma in Infants and Children.—Dr La Fétra (*Archives of Pediatrics*, December) says asthma in infants may simulate bronchopneumonia or a fine bronchitis in their early stages when there is little or no secretion, rapid labored breathing and feeble respiratory murmur, but the low temperature and the dry whistling râles, that flit from one part of the chest to another will suggest the real diagnosis. If such symptoms follow or accompany gastric indigestion, urticaria, or attacks of sneezing, asthma is all the more probable. The existence of eosinophilia, together with the speedy recovery from the attack, and later recurrences will confirm the diagnosis.

The Effect of Large Resections of the Skull.—Schifone sums up the results of an extensive investigation of the processes of repair after cranial resections in dogs by saying that resection of the skull, together with resection of the dura, no matter how extensive, is not a dangerous operation, either in its immediate or remote consequences, always providing that the strictest asepsis has been preserved. Large defects in the skull and dura mater are replaced by dense fibrous tissue, but never by bone. This postoperative growth causes in the superficial layers of the cortical substance a series of changes which involve all its elements, and finally terminate in the replacement of a portion of the nerve elements by neuroglia. In spite of these adhesions and cortical changes, neither disturbances of the motor or sensory functions, nor of nutrition, were observed in the animals, even after a long period of observation. Postoperative cicatricial adhesions do not give rise to the Bravais-Jacksonian epileptic seizures if the healing has been aseptic. If such attacks do occur, it is as the result of individual organic or hereditary predisposition. Hernia cerebri is observed only when special mechanical or inflammatory factors develop, such as increased intracranial tension or meningitis.—*Deutsche Zeitschrift für Chirurgie.*

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 4, 1905.

THE PAN-AMERICAN MEDICAL CONGRESS.

THE report of the fourth Pan-American Medical Congress, from our special correspondent in Panama, the first instalment of which appears in the present issue of the MEDICAL RECORD, will be read with interest. The unfortunate detention of the steamer *Athos*, which was carrying a party comprising most of the delegates from the eastern part of this country and Canada, deprived the Congress of about half the expected attendance, and reduced in like proportion the volume of scientific business transacted. The delay in the arrival of this delegation also caused some apprehension lest disaster had overtaken the ship, and put somewhat of a damper on the social festivities.

In spite of the small attendance, however, the Congress will rank among the successful ones of the series. A large measure of its success was due to the interest centered in the canal undertaking, and naturally much was said of this in the opening addresses. Mr. Tracy Robinson, an American, but an almost lifelong resident of the Isthmus, entertained the members with a historical sketch of the various canal projects, and showed how it was that the present undertaking was the only one holding promise of a successful conclusion. Mr. Wallace, the Chief Engineer of the Canal Commission, spoke at some length regarding the present condition of the work, what was to be done before the completion of the canal, and the engineering problems which had to be solved. The address of greatest interest to medical men was, however, that of Colonel Gorgas, published in full in this issue of the MEDICAL RECORD, in which he spoke of the sanitary problems which lay before him and his associates, and how it was proposed to attack them. Of his ultimate success he seems to have no misgivings, and this confidence would appear to be amply justified by the outcome of his labors in Havana. Of course, a compact city like Havana is very different from a forty-five-mile stretch of open country, yet no one can doubt that Dr. Gorgas will accomplish the task he has set himself, if only the red tape of the Canal Commission, of which there seems to be an abundant supply, does not tie his hands.

The next Congress will convene in 1908 in Guatemala City, if the political condition of the country at the time will permit. At present this city is rather difficult of access from the eastern coast, but in the course of a year or eighteen months Puerto Barrios on the Caribbean side will be connected with Guatemala city by a railway, now building under American direction, and thus the capital will be within easy distance of our Gulf ports. It was thought that one of the northern countries would claim the privilege of entertaining the next Congress, but there seems to have been no one at Panama to extend the invitation. Guatemala will be the fourth Latin-American city in succession to receive the Congress, and it is time interest in the Congress was aroused by a meeting in this country or Canada, otherwise the Pan-American character of the assemblies will be in danger of disappearing. It is twelve years since the first meeting was held in Washington.

THE SANITATION OF RAILWAY CARS.

THE sanitation of railway coaches is a question of vital concern to the general public, and is a matter which has been disregarded too long. Spasms of virtue, doubtless impelled by discussion of the subject in the lay and medical press, have at intervals seized railway authorities, and plans have been propounded with the object of bettering existing conditions. Nevertheless, no practical and effective steps have as yet been taken. The plea is set forth that there are so many obstacles in the way of successfully solving the problem that progress in this direction is necessarily slow. This excuse may have some foundation, but it cannot be that there is no path out of the difficulty.

The report of the Surgeon-General of the Public Health and Marine Hospital Service, for 1904, refers to the subject and points out that the director of the hygienic laboratory has advocated plain, smooth, hard surfaces in railway coaches, that may readily be cleaned, and has shown the dangers of the tapestries, plush and other unsanitary luxuries with which cars are sometimes burdened. He has also called attention to the menace of the open hopper of the water-closet, especially as a means of spreading typhoid fever throughout the country, and has indicated the unsanitary arrangement of the washbowls, as well as the need for a separate sink for teeth-cleaning and throat-gargling processes.

In answer to a request made to the Surgeon-General for suggestions as to the laundering and handling of linen in storerooms and in cars, the following memorandum was submitted: Observation on prolonged trips in Pullman cars has shown that the bed linen used over night is gathered by the porter in the morning and is simply rolled up and thrown into a locker or closet at one end of the car, and that in the process of gathering it up it is more or less violently shaken. It is suggested that this be avoided and that each sleeping car be provided with strong canvas, or preferably waterproof, bags, of sufficient size to hold each a full complement of bed linen from all the berths in the car, and that the porters be instructed to place the used linen into these bags with as little shaking as possible, carrying the bags around the car with them in unmaking the beds in the morning. The bags when full are then to be tightly closed, and the full bags stored in a special locker until the end of the trip. It would be an advantage, of course, if the bags containing the soiled linen could be passed through an efficient apparatus, using steam under pressure, before being sent to the laundry.

Another point which seems worthy of consideration is that the woolen blankets of Pullman cars should be provided with slip covers of cotton, linen, or other washable material. To carry out the plan of the slip covers, the method practised in Germany

of using eiderdown quilts upon beds is suggested. These quilts, from their extreme lightness and the nature of their covering, usually silk, are, while very warm, exceedingly difficult to keep upon the bed. This is guarded against by having the sheets for winter use of extra large size and provided upon one long edge with buttons and upon the other long edge with a corresponding set of buttonholes. When the bed is made up for the night the upper sheet is simply folded upward and inward and buttoned in the middle over the eiderdown quilt, thus inclosing the quilt in a bag as it were, the lower end of which is tucked under the mattress and keeps the quilt in place. This plan would keep the blankets from being soiled and prevent contamination.

The entire sanitary arrangements of both railway coaches and Pullman cars require careful supervision and the introduction of radical reforms. As matters are now, sleeping berths are a distinct menace to health, and it would be well if railway authorities throughout the country would take heart and carry into effect as quickly as possible the suggestions noted above.

The water-closet and washing arrangements of railway cars are disgracefully inadequate and inimical to health, and perhaps no people but the long-suffering American would have endured the present condition of affairs so long. As to the open hopper of the railway water-closet as a source of danger in the spread of typhoid fever, there can be no doubt that it is a fruitful means of disseminating this disease. Attention has been drawn to this fact in the MEDICAL RECORD on several occasions.

Means will be found to remedy all sanitary shortcomings in railway coaches and Pullman cars when those in control of our transportation lines are made to understand that an enlightened traveling public insists that as little risk as possible shall be incurred when en route. Any one who can succeed in bringing this fact home to railway managers will deserve well of the commonwealth. The health authorities of Pennsylvania have under consideration a system of sanitary police for the entire State; the framers of the law will do well to include the inspection of the railroads among the duties of the health officers.

Catching Cold.

THE rationale of the causation of the ordinary "cold" is pretty well understood at the present day and it is generally conceded that when circulatory disturbances or vital depression are produced as the result of localized or general chilling of the body surface, newly entered or already present pathogenic bacteria are enabled to attack the body with very good chances of success. At such times it is said that the powers of resistance are below par, and consequently the bacteria gain an easy victory. This point was illustrated in telling fashion by Dürck, who found that rabbits infected with pneumococci developed pneumonia if they were subjected to severe cold, whereas unchilled control animals survived. The mechanism of this weakening of the vital forces has not been satisfactorily explained, however, and considerable interest, therefore, attaches to experimental work on the subject recently done by Franz Nagelschmidt. This observer contributes to the recent Senator *Festschrift* a description of his studies on the hemolytic and bactericidal power of the blood after the animal has been exposed to cold. Rabbits and goats were used, and the activity of the antibodies of the serum was tested before and after immersion of the whole animal or portions of its body in ice water for varying lengths of time. The results obtained showed some curious inconsistencies that still demand explanation, but in general it may be said that by chilling the surface it is possible to reduce the number of antibodies in the blood to a very marked degree. This means that the body is deprived of a goodly proportion of its defensive weapons, and therefore under such conditions it easily falls a prey to infections of all sorts. The effect of cold in bringing on attacks of paroxysmal hemoglobinuria is well known, and it may be that this obscure condition will be illuminated by further developments along the same line of investigation. A point of practical importance is the fact that it was found that repeated exposure to slight degrees of cold brought about an increase of antibodies, and this observation therefore affords a theoretical justification of the practically approved methods of "hardening" the body by hydrotherapeutic and other methods of training. Such procedures should not only serve to protect against colds and allied conditions, but also should render the body better able to cope with bacterial and other noxa of all kinds.

The Use of Ambulance Dogs in War.

IT is well known that dogs, of certain breeds especially, have a considerable amount of intelligence. As the constant companion of man through generations, the brain of the dog has been developed, until at the present time it is probable that this animal can be more easily trained than any other. For something like eighty years, the monks of St. Bernard have trained and used dogs to rescue travellers lost in the snow. In Europe many of the armies, inspired by this idea, employ dogs to seek out the wounded on the field of battle and thus aid in the work of the ambulance corps. In Germany dogs are attached to the ambulance service in many regiments, and were employed in the Herrero expedition in Africa. In Austria, France, Italy, Switzerland, Holland, Russia, and America dogs are utilized in ambulance work.

The *British Medical Journal*, of December 10, 1904, contains a special article on the subject and describes the methods pursued in training and using dogs for this purpose. With the object of rendering first aid to those men who are not mortally wounded, the writer says, the dog is equipped with a waterproof canvas saddle, with a pocket at each side. In these pockets are placed eight triangular bandages, while slung around the dog's neck is a small cask of brandy or rum, and a bell for use after dark. If the wounded man be strong enough, he may take the bandages and temporarily bind his wounds, and he can also help himself to stimulants. Supposing him to be too weak to take advantage of this temporary assistance, the dog barks loudly until he attracts the notice of the search party.

Several officers of the British Service have been experimenting with dogs in order to satisfy themselves whether they are calculated to be of a value in the rôle of ambulance assistants. These men have reported favorably, but as yet the British War Office has made no move. However, as the British War Office has the reputation of being the most hidebound and conservative of all the notoriously conservative State departments of that country, this is not to be wondered at. As a matter of fact, the scheme is but in its experimental stage and needs to be weighed carefully before it is adopted on a large scale. Its humanitarian side cannot but appeal to all, and if the use of dogs is found practicable and of value, it will be another step in the direction of ameliorating the horrors of war.

Serum Treatment of Syphilis.

IT is the fashion at the present day to search for a specific treatment for all diseases known or believed to be due to the action of a pathogenic microorgan-

ism. Although the number of diseases in which a true curative or prophylactic serum has been obtained is discouragingly few, the search goes on. Recently the attempt has been renewed to elaborate a curative serum for syphilis with the usual initial success or supposed success. A. Risso and A. Cipollina, writing in *La Riforma Medica,* of November 30, 1904, give us the results of experiments made by them in the preparation and use of this antisyphilitic serum. The source of their serum was a number of dogs which were treated by subcutaneous and endoperitoneal injections of blood obtained from patients in the secondary stage of syphilis who had not received any antisyphilitic treatment. The injections were repeated three or four times at intervals of five or six days. The blood from these animals was taken a week after the last injection, and the serum was made so as to contain not only the blood serum of the animal, but also the active principle, so to speak, of the corpuscles and solid contents of the blood. The serum, the authors say, is made from as near a pure culture of syphilis as the lack of knowledge of the pathogenic germ allows us to get. The patients treated by injection of this serum were sixteen in number, fourteen in the secondary and two in the tertiary stage of syphilis, who had not yet received antisyphilitic treatment. The authors claim that all of the patients treated were benefited by the treatment; all the papular and macular skin lesions disappeared more quickly than under mercurial treatment, and even the mucous lesions disappeared without local applications. Nine patients were cured so far as any active symptoms were concerned. In one case a gumma of the nose disappeared after twelve injections. Four other patients were much improved. The disadvantages were insignificant, consisting of slight fever, local pain, or an eruption. The authors believe that their serum has true specific action on the disease, while it also probably acts as a stimulant to the tissue elements, or favors the absorption and destruction of the inflammatory elements of the disease.

For an Assistant Sanitary Superintendent in Brooklyn.—Application has been made to the Supreme Court in Brooklyn for an order directing the Board of Health of New York to show cause why an Assistant Sanitary Superintendent for the Borough of Brooklyn should not be forthwith appointed. The vacancy is stated to have existed since last August.

King Edward's Daughter Operated upon for Appendicitis.—The Princess Victoria, daughter of King Edward, underwent an operation for appendicitis on January 31. The operation was performed by Sir Frederick Treves, sergeant surgeon in ordinary to the king. A bulletin subsequently issued stated that the operation was successful and that the patient had rallied satisfactorily.

Changes in the Management of the State Hospitals.—It is reported that Mr. Homer Folks, former Commissioner of Charities in New York City, has had a consultation with Gov. Higgins on the latter's recommendation that the State insane asylums and hospitals be restored to the management of the local boards under which they were until Gov. Odell put through legislation abolishing such boards. A bill embodying the Executive's views will be drawn up by the New York charities expert and no doubt will be passed early in the session. Another bill which Mr. Folks will draw up will give the State Board of Charities power to order inmates of charitable institutions transferred from one institution to another. The financial affairs of State hospitals are to remain vested, it is understood, in the fiscal supervisor.

News of the Week.

Medical Society of the State of New York.—At the annual meeting of the State Society, a report of which appears in this issue of the MEDICAL RECORD, the following officers were elected: *President,* Dr. Joseph D. Bryant, New York City; *Vice-President,* Dr. Herman R. Ainsworth, Addison; *Secretary,* Dr. Frederick C. Curtis, Albany; *Treasurer,* Dr. O. De V. Ball, Albany.

A Generous Gift to the Academy of Medicine.—Dr. A. Jacobi, ex-president of the New York Academy of Medicine, has purchased the complete collection of monographs belonging to the late Prof. Gerhardt and presented them to the Library of the Academy. There are 5,000 titles in the collection.

The Needs of the Army Medical Corps.—Captain Peyton C. March, U. S. A., who was a military attaché with the Japanese army in Manchuria, has made a report to the War Department in which he expresses the opinion that the medical corps of the United States Army would be entirely inadequate to handle the great sanitary problems which would arise in the event of a great war. "Whatever may be the theoretical arguments," he writes, "offered in opposition to the increase in our medical corps asked for by the Surgeon-General last winter, my experience here has convinced me that the General Staff should put itself on record as approving and recommending such an increase. Our present medical corps, assisted by the volunteer and State surgeons, upon whom we could rely in time of war, will, in my opinion, be wholly inadequate to the task of handling the sanitary problems of a great war, and in that emergency it will be extremely ill for the General Staff if it can be stated in truth that the number and grade of officers desired by the Surgeon-General to render his corps able to handle those problems have not been authorized because of the opposition of the General Staff."

Yellow Fever at Panama.—Three deaths from yellow fever have occurred on the U. S. cruiser *Boston,* in the harbor of Panama, and several others of the officers and crew are ill with the disease. Among those who died was Dr. Kohlhase, surgeon of the ship. The vessel has been ordered to proceed northward to Puget Sound, or any other locality her commander sees fit. It is stated that since July 1 there have been eighteen cases and three deaths on the Isthmus. Gov. Davis, of the Canal Zone, reports that a systematic fumigation of the entire City of Panama is now being made, and that, with the increasing force of men now engaged in mosquito extermination work, Chief Sanitary Officer Gorgas confidently believes that all mosquitos capable of transmitting yellow fever will be destroyed within a month.

Instruction in Public Health.—Beginning with the next session, a course in public health will be included in the curriculum of the medical department of the University of Pennsylvania. The course will include sanitary engineering, sanitary legislation, inspection of meat, milk, and other animal products, the sanitary engineering of buildings, social and vital statistics of the United States, practical methods used in sanitary work, general hygiene, and personal hygiene.

Mt. Sinai Hospital Alumni.—The eighth annual reunion and dinner of the Associated Alumni of Mt. Sinai Hospital was held on Wednesday evening, January 25, 1905, at the rooms of the Freundschaft Society. The following officers were elected for the ensuing year: *President,* Dr. Fred. Mandlebaum; *Vice-President,* Dr. Louis Housewirth;

Treasurer, Dr. Andrew Green Foord; *Secretary,* Dr. Leo B. Meyer.

Academy of Medicine of Toledo and Lucas Co., O.—At a meeting held January 13, the following officers were elected: *President,* Dr. Thomas Hubbard; *Vice-President,* Dr. Dice; *Secretary,* Dr. Levison; *Financial Secretary,* Dr. Duncan; *Treasurer,* Dr. John Keller; *Board of Censors,* Dr. Hasencamp; *Delegate to State Society,* Dr. Myers.

Cincinnati Water Supply.—It is probable that alum will be used for clarifying the city's water supply as soon as the new water works are in operation, unless something better is discovered. The commission is also considering the roofing over with concrete of the new 45,000,000 gallon reservoir.

Cincinnati Medical Library Association.—At a recent meeting of this association reports were read by the Secretary, Treasurer, Librarian, and President. The Executive Committee was instructed to have the Association duly incorporated under the State laws. Officers were elected as follows: *President,* Dr. Henry W. Bettmann; *Vice-President,* Dr. Joseph Eichberg; *Treasurer,* Dr. Wm. H. Crane; *Librarian,* Dr. Arch. I. Carson; *Secretary,* Dr. Alfred Friedlander.

Annual Dinner of St. Louis City Hospital Alumni.—The annual dinner of the Medical Society of City Hospital Alumni, St. Louis, was held Thursday evening, January 5, at the Mercantile Club. There were present seventy-five members and guests. The newly elected President, Dr. John Green, Jr., delivered an address on "Municipal Institutions for the Care of the Sick Poor," contrasting the systems prevalent in neighboring cities with that which exists in St. Louis. He pointed out the evils of the local system, and suggested measures for relief. The following gentlemen responded to toasts: Drs. K. W. Millican, F. L. Henderson, Amand Ravold, M. A. Bliss, John Young Brown, H. Tuholske, and George Homan.

St. Louis Free from Typhoid Fever.—No deaths from typhoid fever occurred in St. Louis during the week ending January 21, and but one case was reported. The total number of deaths for the week was 221, of which 29 were due to pneumonia.

Attempt at Suicide No Crime.—If a bill introduced at Albany repealing Section 178 of the Penal Code becomes a law, it will no longer be a crime to attempt suicide. It is claimed that as it stands the law is a dead letter anyway, for there never is a conviction with sentence for this offense.

No Yellow Fever in Mexico.—The President of the Superior Board of Health of Mexico announces that as a result of the government's campaign against yellow fever, the disease has been practically stamped out and that there is not a single case in the country at present.

A New Field for Radiotherapy.—The office of a genito-urinary "specialist," well-known to the readers of newspaper advertisements in this city, was raided last week by the police, and the two "doctors" and a clerk in charge were locked up in the Tombs. The evidence by which the indictment was secured was based mainly on an investigation conducted by Champe S. Andrews, Esq., counsel for the County Medical Society. It was learned by the assistance of a detective, who posed as a wealthy Western woman, that nearly $10,000, the saving of a lifetime, had been mulcted from a carpenter who was being treated for alleged Bright's disease by means of "radium." This was supplied in ounce bottles, costing the victim $1,500 each, and which required frequent renewal. Analysis of the solution of course showed no trace of radium. When the arrest was made, thirty-five well-dressed women were waiting in the sumptuously furnished reception-room of the "doctor's" office.

Needs of the Immigration Service.—Frank P. Sargent, Commissioner-General of Immigration, has submitted to the Committee on Appropriations at Washington a statement of the necessity of permanent improvements for the immigration service at New York and San Francisco. At Ellis Island, he said, it is desired to construct a contagious disease hospital, at an estimated cost of $250,000, and a $12,000 water purification plant. At San Francisco an immigration station is needed on Angel Island, plans for which have been made, the station to cost $250,000.

Subway Sanitation.—The authorities in charge of the subway have added another to the means for the dissemination of germs they have already provided. By dropping a nickel into a slot, access is gained to a comb, brush, towel, and soap, with which those not versed in bacteriology may inoculate their persons.

Suspected Cases of Pneumonic Plague.—Considerable excitement was caused last week on the arrival of the *Vaderland* from Antwerp, when it became known that ten of the steerage passengers had died of pneumonia during the trip. Some of the features about the epidemic seemed so suspicious as to cause Health Officer Doty to quarantine the vessel and those of the immigrants who had not yet landed until a bacteriological report on the nature of the diesase could be made. The conclusion was promptly reached that the deaths were not due to the plague.

Dr. L. F. Barker has been appointed professor of medicine in Rush Medical College, Chicago.

Journal Devoted to First Aid.—In March a first aid magazine will be established in Chicago, to be issued monthly as the organ of the American White Cross First Aid Society. Among the members of the editorial staff are Drs. Frank Billings, Nicholas Senn, Geo. W. Webster, John B. Murphy, J. B. Herrick, John Ridlon, N. S. Davis, Chas. Adams, Henry B. Favill, and Wm. E. Quine.

The Ethics of Large Type.—At a stated meeting of the Medical Society of the County of New York, held December 27, 1904, the following resolution was unanimously adopted: "That in any directory or list other than a medical one, it is undesirable that any data should appear other than the name, address, and telephone number, and that the use of more prominent type for one name than another is to be severely deprecated."

Arrest of a Coroner.—District Attorney Jerome recently caused the arrest of one of the coroners in this city on a charge of attempted bribery. He was accused of having offered one of the assistant district attorneys $200 if he would drop the indictment against an abortionist recently apprehended.

A Test of Christian Science.—A bill has been introduced in the Iowa Legislature forbidding Christian Science "healers" to practise their art in the State under penalty of imprisonment in the penitentiary. The introducer of the bill has promised to withdraw it if the Christian Scientists will cure the doorkeeper of the house of deafness. Some of the "healers" are not willing to accept the challenge, but others believe that this is the appointed time to make a great demonstration of their powers in the most public way and propose to organize a concert of prayer and hard thinking for removal of the doorkeeper's belief that he cannot hear.

Consumptive Teachers Barred from Public Schools.—The Jersey City Board of Education has adopted a resolution that no teacher shall be permitted to continue his or her work in the classroom who has tuberculosis. It has also made a rule that teachers thought to have tuberculosis must submit to an examination by a physician to be designated by the Board of Education.

Hospital News.—*Bequests to Trenton Hospitals.*—The managers of the three public hospitals in Trenton, N. J., have been notified that each institution is to be given an amount aggregating $35,000 for the establishment of free beds in memory of the late Dr. James D. Tantum, who recently died from the effects of an operation in a Philadelphia hospital. He left no will, but on his deathbed requested his daughter and sister to give from his estate $35,000 to three hospitals in Trenton and $5,000 to the German Hospital in Philadelphia.

Gift to the Brooklyn Hospital.—This hospital has received $1,500, given in memory of Gen. Alfred C. Barnes by his son and daughter.

The Post-Graduate Medical School and Hospital.—An anonymous friend has presented $5,000 to this institution for the needs of the hospital.

New Rule for Cook County Hospital Staff.—At a meeting of the staff of this hospital, held December 13, President Brundage made the rule that the members who do not visit the hospital at least three times a week, or are absent more than three successive days without an excuse of illness, are to be asked for their resignations, and their places will be filled by the nominating committee.

Stony Wold Sanatorium.—The annual report of the officers of this institution shows that since its incorporation in 1901, 131 patients have been cared for, some of them staying over a year. Of seventy-two patients taken care of last summer in the buildings and camps only seven were assisted by their families. In order to carry out the work on the plans desired more dormitories and a larger income are needed.

Fresh-Air Homes for Consumptives.—The Society for the Prevention of Tuberculosis has accepted the gift of a fund made by W. H. McClain of the St. Louis Provident Association, on behalf of a person whose identity is not disclosed, which will permit the establishment of a fresh-air colony for consumptives. The offer includes a tract of land on the Iron Mountain Railroad near Montesano Springs, Mo., about twenty-five miles from St. Louis. It is proposed by the donor to erect on the tract a pavilion to be used as a hospital and administration building and many small fresh-air pavilions of from one to six rooms each for such patients as may desire to purchase them, the use of the ground being given free.

The Evangelical Deaconess Home and Hospital has decided to erect a new hospital on the site now occupied by that institution in St. Louis. The decision to erect a new hospital was reached after the annual report had been read showing that 300 patients had been turned away during the year on account of lack of room. The annual report showed 837 patients had been treated during the year; of this number 192 were treated without charge. The treasury showed a balance on hand of $9,345.

Presbyterian Hospital for St. Louis.—The Presbyterians in St. Louis have launched a project which it is hoped will result in giving that denomination a new and modern hospital, to cost $1,000,000. There is said to be no hospital of any consequence under the control of that church west of Chicago.

Philadelphia Home for Incurables.—The new cancer annex for men recently erected at a cost of $60,000 was opened on January 28. The building is a three-story brick structure, with accommodations for twenty-five patients. Especial care has been taken in the construction to guard against contagion, the floors being tiled and the doors without moldings.

Bequest to the Philadelphia Hospital.—By the will of the late Francis T. Fassett, of Philadelphia, the sum of $5,000 is devised to the Children's Hospital for the maintenance of a free bed to be known as the Anna Avour Fassett Bed.

Jewish Hospital of Philadelphia.—The following appointments are announced as additions to the present staff: Dr. Chas. P. Noble, consulting surgeon; Dr. Lawrence F. Flick, consulting physician; Dr. Wm. H. Randle, obstetrician; Dr. Joseph B. Potsdamer, pediatrist; Dr. Sidney L. Feldstein, radiologist.

Obituary Notes.—Dr. Edward L. Cunningham, of Newport, R. I., died January 24 at his home in that city, in the ninety-sixth year of his age, after an illness of less than a week. He was the oldest graduate of Harvard University, graduating at the head of the class of 1829. One of his classmates was Dr. Oliver Wendell Holmes. He was born in Boston, and removed to Newport thirty-three years ago. He was never in active practice, but his life was devoted to literary pursuits.

Dr. Cordelia A. Greene died at the Presbyterian Hospital in this city, on January 29, following an operation, at the age of seventy-four years. She was a graduate of the Western Reserve College of Cleveland in the class of 1857, and of the Women's College of Philadelphia. Later she studied under her father, Dr. Jabez Greene, at Clifton Springs and Castile, N. Y. On his death she took charge of the sanatorium at Castile. She was a member of the American, the New York State, and the Wyoming County Medical Association.

Dr. Patrick J. McGrath died in this city on January 29, as the result of a fall. He was a Dublin graduate, and came to this country shortly before the Spanish war. He served as contract surgeon in Cuba and the Philippines, and had just received an appointment as surgeon in the Panama Canal Zone.

Dr. Joseph A. O'Neill, a contract surgeon in the army, was killed by a band of ladrones at San Francisco de Malabon, Cavité Province, P. I., on January 24. He was formerly a resident of this city, and was a graduate of the Albany Medical College in the class of 1897. He was appointed a contract surgeon in August, 1900, and had since been on service in the Philippines.

Dr. T. H. Brenneman, formerly house physician at St. Vincent's Hospital and recently physician at the Princess Anne Hotel, Virginia Beach, died January 28 at the Sarah Leigh Hospital, Norfolk, Va., aged 34 years. The cause of his death was septicemia, contracted while performing a surgical operation in this city two or three weeks ago.

Dr. Edward Howard Craven died at Philadelphia on January 19 at the age of 83 years. He was a graduate of Jefferson Medical College.

Dr. Edwin Hellyer died at Philadelphia on January 20. He was graduated from Long Island College Hospital in the class of 1864, and he was chief surgeon to the National Guards Hospital of Philadelphia during the Civil war.

Dr. Otto Koehlhase, assistant surgeon, U. S. Navy, died of yellow fever on the cruiser *Boston* in the harbor of Panama on January 28. He was appointed to the navy in May, 1903, when he was made assistant surgeon. His station on the *Boston* was given him last November and was the beginning

of his first cruise. Prior to that time he was on the cruiser *New York*. Last March he was graduated from the Naval Medical School in Washington. He was 27 years of age.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

MR. CHAMBERLAIN AT THE LIVERPOOL SCHOOL—ROYAL COLLEGE OF SURGEONS SCHOLARSHIPS—THE PHYSICAL DEGENERATION REPORT; OFFICERS OF HEALTH, TEACHERS' CONFERENCES, ALCOHOL [illegible].

LONDON, [illegible]

YESTERDAY was a red-letter day for tropical medicine and Major Ronald Ross, who delivered a lecture on the recent rapid progress of our knowledge of malaria, etc. The address was attended by Mr. and Mrs. Chamberlain, who were staying with the Earl and Countess of Derby, and by them and other visitors, including the Princess Christian. They drove over to Liverpool for the purpose. Major Ross, as you will anticipate, gave a masterly account of the subject, and paid a high tribute to Mr. Chamberlain for having listened when Colonial Secretary to those who knew something of the matter. He also recounted the work of Americans in the Panama Canal works.

Mr. Chamberlain moved a vote of thanks to Major Ross for his interesting and somewhat alarming address and congratulated Liverpool on being in the very first rank in investigating these diseases and on having been able to secure the services of so competent an observer as Major Ross. Such scientific workers he numbered among the founders of the Empire.

Yesterday, at a meeting of the Council of the Royal College of Surgeons, a report was presented by the president and vice-presidents respecting an offer made by Mrs. Macloghlin, to give £10,000 to endow scholarships to assist young students in need of financial help to proceed with their studies. The offer is made in accordance with an intention of her late husband and in memory of him. The council gratefully accepted the offer and agreed to administer the trust as arranged by the president and vice-presidents, in consultation with Mrs. Macloghlin.

Mr. Owen, on behalf of Mr. Edward Atkinson, of Leeds, presented the college with six saws, invented and used by William Hey, for operations on the skull.

The Society of Medical Officers of Health has been discussing the report of the Inter-Departmental Committee on Physical Degeneration. Among the recommendations of that committee is one that a physical census of the people should be taken, beginning with children in schools and factories and extending gradually over the whole population. Periodical measurements of the children should be taken, and, as medical officers would have to instruct the children, Sir Lauder Brunton, who opened the discussion, thought the society a suitable one to consider the proposal, the more as judicious training necessitates a preliminary medical examination, so that exercises may be adjusted to strengthen weak parts. The feeding of the children being of prime importance, Sir Lauder proposed that a kitchen should be attached to every school, where the girls could learn to cook, and the medical officers could lecture to the parents on food and food value. Meals could be thus provided for all who could pay, and for those who could not subscriptions could be raised, or, failing them, the rates must be called upon.

Sir John Gorst, M.P., eagerly supported the last suggestion. He has been traveling about the country for several months advocating the supply of meals to school children, many of whom are insufficiently fed to enable them to profit by the instruction provided. It is not surprising that the ex-ruler of the education department should in this way have shocked his university and that he should have been charged with socialistic tendencies and challenged to resign his seat. But he has no notion of doing so and says he will contest it again at the next election.

Other speakers urged that it would be wrong to diminish parental responsibility and that it was desirable to find means of training the benevolent woman, who was an important asset in national health, but lacked knowledge.

Apart from the health question, the educationalists have been forcing their views forward by means of several conferences. Head masters, assistants, and other teachers have had their meetings—each rank apparently convinced of its own importance and dissatisfied with its remuneration. The schoolmaster has, indeed, been abroad the last week or two, and his claims to a hearing have been attentively listened to. He has said some wise things and not a few foolish ones. Among the latter I put the assertion that a boy cannot learn two languages at once. I know boys who have learned three and four without difficulty. Coming almost as a pendant to the teachers' conferences was the meeting of the Classical Association, when the new president, Lord Chancellor Halsbury, delivered his address. He placed the highest value on Latin and Greek, but he would have them studied, not to pass examinations in grammatical minutiæ, but for the enjoyment of being able to read them easily. He would not undervalue accurate scholarship, but would not begin with an attempt at accurate grammar. If a teacher insisted on the nuances of grammar before a pupil could read a language, it might risk his hating it for the rest of his life. He deplored that so few classical authors were read, and suggested a wider curriculum as sure to lead to a perusal of a wider classical literature.

Mr. McAdam Eccles was one of the witnesses examined by the Committee on Physical Deterioration, and he has for a long time given much attention to the effects of alcohol in that direction. On Tuesday he opened a discussion on the subject at the Society for the Study of Inebriety. He distinguishes deterioration from degeneration, the former being a decline in the economic value of the organism produced by a change in the cell, the latter rather a decline in morals. Direct alteration in the cell may be demonstrated microscopically, and it is almost universally admitted that alcohol acts on it both directly and indirectly. Direct action on the individual varies enormously on account of the personal equation. Probably the younger cells are more easily affected. Hence the growing tissues of children are quickly deteriorated. He was of opinion that many instances of rickets were due to alcohol in the mother's milk. He held, too, that in old age alcohol was a potent factor in wearing out the human body. The close connection between drink-craving and bad housing, he thought, was self-evident. Bad cooking was also responsible for much. Fatigue and excitement both engendered a thirst for alcohol, and through it led to deterioration. Want of fresh air deprives the drinker of oxygen needed to destroy the alcohol. The indirect effects were more pronounced, especially in childhood. Both before and after birth the mother's drink told upon the infant. If both parents were given to drink, the progeny would deteriorate in every way and the future of the race be imperilled. The facts demand consideration in reference to the efficiency of the nation. Life assurance statistics proved that total abstainers enjoyed greater longevity than moderate drinkers.

In the discussion that followed Dr. Robert Jones, whose experience at the County Council's Asylum, at Clabury, is important, expressed the conviction that mental disease was largely due to alcohol. He reckoned that twenty-seven per cent. of lunatics in asylums were there through alcohol. He thought the masses of the people must learn to realize that it is bad form to be drunk.

Dr. Hyslop, of Bethlem Hospital, asked: "What shall it profit a nation if it gain the whole world, but lose its own mind?" Could the nation be considered prosperous while, out of proportion to the increase of population, more asylums and poorhouses had to be built, when one person in every 33 was a pauper, and one in every 238 was a lunatic? The British constitution and character were both deteriorating—and mainly through the consumption of alcohol.

Drs. Beach, Stewart, and Dunn also spoke in enforcement of the views expressed in the paper.

Another nonogenarian doctor has passed over to the majority, Dr. William Williams Morgan, who died in his ninety-fifth year, at Newport, where he settled soon after he took his diplomas (in 1835-36). He took the M.D. St. Andr. in 1862. In his early days he was present during the Chartist riot in the town and attended the wounded where they fell, at great risk to himself. He was probably the oldest practitioner in the country.

Sir James J. D. Louis Donnet, K.C.B., M.D., died on Wednesday, in his eighty-ninth year. He entered the navy in 1840 and had had a distinguished career. In 1875 he became inspector-general of hospitals and fleets. During his active service he was engaged on the coast of Syria in 1840-41, in Fiji in 1848, on the coast of Kamchatka 1854-55. He was also in the Arctic Expedition of 1850-51. He served on various committees in connection with naval matters. He was honorary physician to Queen Victoria and to King Edward. He contributed papers on fevers, dysentery, infections, leprosy, etc., at intervals from 1867 to 1889.

The death is announced of Dr. Peter Murray Braidwood, of Newbury, at the age of sixty-three. He was the founder of the Children's Hospital at Birkenhead. He took the gold medal for his thesis at Edinburgh, 1863. He won the Astley-Cooper Prize in 1868, on Pyemia, and held the Boylston Medical Prize of Harvard. He had been president of the Royal Medical Society of Edinburgh, and an examiner in medical jurisprudence to the university. He contributed various papers to the societies and journals.

OUR PARIS LETTER.

(From Our Special Correspondent.)

MEETING OF THE "EXTERNAT" AND "INTERNAT" OF THE PARIS HOSPITALS—TOXICITY OF ILLUMINATING GAS—PROPHYLAXIS OF HYDATID DISEASE—TREATMENT OF NEOPLASMS OF THE BREAST BY RADIOTHERAPY—LACERATION OF THE ESOPHAGEAL WALL—THERAPEUTIC USE OF THE SALTS OF RADIUM—GONOCOCCIC PUERPERAL POLYARTHRITIS—RELATIONS BETWEEN THE CHEMICAL CONSTITUTION OF MEDICINES AND THEIR THERAPEUTIC ACTION—A NEW METHOD OF TRACHEAL INJECTION.

PARIS, December 26, 1904.

EVERY year, in December, the meeting of the Internes of the Paris hospitals takes place. First of all, medical students, in order to attain the dignity of the position of hospital internes, must come up before the "Externat," the association which confers the title of hospital externe. The hospital externes are nominated at the meeting for a period of three years. The first oral examination, lasting five minutes and relating to a question in anatomy, decides the question of the aspirant's eligibility for admission. Definite admission is granted only after a second oral examination of five minutes, relating to a question in pathology. Once nominated, the work of the externes consists of various duties in the hospitals—the observation of patients, surgical dressings, and playing the part of assistant in surgical operations. Only hospital externes who are nominated for a period of three years are eligible to the position of interne. There are always many candidates, seven hundred to eight hundred externes applying for forty or fifty places open to internes. The examination for this position consists of two parts: One, a written paper on some anatomical and on some pathological question, for which two hours are allowed; besides this, an oral question in anatomy, and one in pathology, for which ten minutes are allowed. The first examination makes the candidate eligible, while the definite admission depends upon the second examination. The hospital internes are nominated for a period of four years. They supplement the work of the chief, and act as principal assistants at surgical operations. Besides this, they serve as a special corps who are on call both day and night in all the hospitals. They are called on for emergency operations, and it is their duty to decide upon the suitability of patients who present themselves for admission. The meeting took place this year on December 19. The written questions drawn by lot by one of the candidates were "Radial Nerve," "Symptoms and Diagnosis of Tabes."

Apropos of the recent tragic death, inexplicable in all of its details, of the deputy of Paris, Syveton, there has been conducted a series of researches concerning the toxicity of coal gas. It is evident that one can be intoxicated by gas from even the best constructed chimneys. It suffices for this if the chimney draw badly, thus leading to a damming back of the products of combustion, a condition which is always possible. The peculiar odor of this gas constitutes a sufficient safeguard, when it accumulates rapidly. When, on the contrary, it accumulates slowly, insensibly, one becomes accustomed little by little to the odor, and becomes intoxicated by carbon monoxide gas. Ordinary coal gas contains from about 8 to 10 per cent. of carbon monoxide. According to the studies of Gréhant, when this gas is mixed with respired air in the proportion of 1 to 300, the mixture is very dangerous, and is poisonous enough to cause death.

At the Academy of Medicine, Blanchard read a very interesting paper on hydatid disease, written by Dévé of Rouen. It is known that hydatid disease, an affection common to man and animals, is transmitted almost always by the dog, although secondarily by the cat. Domestic carnivora infect themselves by eating the viscera of cows, pigs, and sheep, which have been infested by fertile echinococci. Prophylaxis of this disease, in man as in animals, ought to aim before all to suppress the infection of the dog. Severe measures should be taken, such as the following: The seizure in the abbattoirs, and the effective destruction by incineration, of all viscera infected with this disease. Strict regulations concerning the entrance of dogs into the public abattoirs. The posting of notices in both public and private abattoirs, calling attention to the danger of feeding these contaminated organs to dogs and cats. Veterinary inspections, having for their object this anti-echinococcic prophylaxis. The conclusions of this report were adopted by the Academy.

At the annual meeting on December 13, the Academy awarded the prizes which it gives every year to its laureates. Finally, at the meeting of December 20, the Academy elected its officers for 1905. The new president is Léon Collin, and the vice-president, Guéniot.

At the Surgical Society, Béclère reported the results of his experience with radiotherapy as applied to neoplasms of the breast. The technique which he followed in his work took cognizance of the following rules: At each sitting, he gave the maximum quantity of rays, compatible with the integrity of the skin. In reality, it was difficult to exceed 4 H (Holzknecht unit) at one sitting. The maximum interval of time compatible with the integrity of the skin was allowed between the sittings. A period of at least a week always separated two consecutive sittings. Béclère concluded that in all cases of neoplasm of the breast—those recurrent after surgical intervention, or considered inoperable—radiotherapy is the treatment of choice, capable of bringing about a local cure, of ameliorating the general condition, of prolonging life, or more or less alleviating the last sufferings.

Pierre Sébileau showed a specimen with a large laceration of the esophageal wall, caused by an attempt to extract a piece of money from an infant two and one-half years old. This laceration was caused by Graefe's instrument. In order to extract a five-centime piece which the child had swallowed, Sébileau's assistant inserted Graefe's instrument into the esophagus with no difficulty. But when he tried to withdraw it, it was arrested, and slight pulling did not suffice to raise the obstacle. Introducing his index finger into the pharynx, the operator was able to draw out the instrument without being able to dislodge the foreign body. Some hours later the child showed all the signs of acute pulmonary congestion. One would have called it an acute attack of capillary bronchitis, a true suffocative catarrh. Eighteen hours after the operation, the child died of progressive suffocation. Autopsy revealed a laceration of the posterior esophagopharyngeal wall, as well as two others situated lower down at the point where the esophagus enters the mediastinum. These lacerations were caused by the sharp edge of the coin, which was very old and worn. When the coin, disloged by the instrument, was drawn up by the esophagus, its edge incised the walls and gave rise to the accident.

At its last meeting, the Surgical Society nominated its officers for 1905. The president is Dr. Schwartz; vice-president, Paul Segond; general secretary, Ch. Nélaton; archivist, Broca.

At the Hospital Medical Society, Béclère spoke of the therapeutic employment of the salts of radium. In the action of these salts, it is necessary to distinguish induced radioactivity due to gaseous emanation and radiation, the latter alone being employed in therapeutics. Its effects are similar to those of the Roentgen rays. The measure of the intensity of its effects serves to indicate the activity of the salt employed. Among these methods, physicians by preference employ the electrical method. It is based on the property of radium, which renders the air a conductor for electricity. Physicians prefer the electrical method for the dosage of radium salts, another method founded upon the partial absorption of radiation by a body having almost the same thickness, if not the same chemical composition, as the skin. Since the haloid salts, alkaline, are colored under the influence of radium rays, there is every indication to employ in radiotherapy, the chromometric method. The honor of this discovery belongs to Dr. Guido Holzknecht, privat docent of medical radiology at the University of Vienna. It was in 1902 that he invented his chromoradiometer, which has contributed so much to the progress and to the extension of radiotherapy. The radium salts in their application to the skin appear to exercise an important effect on the surface, but, on the contrary, only a very slight action at any depth. Radium rays offer the great advantage of being capable of being applied to regions where the employment of Roentgen rays present great obstacles. This is true in relation to the natural orifices, where it is very difficult to make the Roentgen rays penetrate. The chief indication for the therapeutic employment of radium salts is, therefore, the treatment of lesions of small extent and of little depth, the anatomical position of which renders the application of Roentgen rays difficult.

Mosny also cited an extremely interesting case of puerperal polyarthritis of gonococcal nature. Gonococcic infection, often latent in a woman, can develop at the time of labor. Such was the case with this patient, who, without every having had any other symptoms of this disease, except a vaginal discharge, which is very common, developed, after a normal confinement and without any serious consequences to the child, a polyarthritis, the true cause of which bacteriological examination alone was able to determine. It was due to a latent gonococcic infection, which was lighted up by the confinement. The chief point in this observation is the possible absolute latency of gonococcic infection. This is clearly shown in the absence of every blenorrhagic manifestation in the genito-urinary passages of this patient. Nothing in the past history of the patient was at all suggestive of the existence of gonorrhea. Nothing in her present state would have authorized a suspicion of this infection, since the child had no ophthalmia, and the examination of the mucous exudates from the vagina, from the cervix, and from the urethra, gave no sign of the disease. But very

careful bacteriological examination revealed beyond a d[illegible] the presence of gonoccoci in pure culture in the purulent exudate of the knee.

At the Society of Internes, Dr. Albert Robin gave a very interesting talk on the relations which exist between the chemical constitution of medicaments and their therapeutic action. He concluded by showing the unlimited field that synthetic chemistry opens to therapeutics. Chemical affinities will some day be able to adapt themselves to any given therapeutic action, and it will be possible to create by the miracle of synthesis, medicaments which shall be suitable for any disease which one wishes to treat.

Mendel explained to the society a new method of making tracheal injections, much less troublesome to the pati[illegible] than the laryngological proceeding, and far more easy to practise, since it necessitates no special preparatory instruction. The tracheal injection forms the basis of a rational and powerful medication of chronic bronchopulmonary affections, and especially of tuberculosis. The proceeding is simplified if the tongue of the patient is held outside of the mouth, for then the pharynx will form a funnel in which the only orifice is the glottis. For the digestive tract is closed only for deglutition, and if the patient abstains from swallowing, then the liquid proje[illegible] onto the wall of the pharynx runs down into the air-passages. Mendel demonstrated this method to the society to prove its practical working. He injected in this simple way [illegible] of eucalyptus, which had been [illegible] patient had been tracheotomized. A short time after the injection the patient was asked to cough, and he expelled by the tracheal wound a large quantity of the injected oil. The injection was thus proved to have perfectly fulfilled [illegible] object.

Progress of Medical Science.

The Boston Medical and Surgical Journal, January 26, 1905.

Gastroenterostomy. (A Preliminary Note.)—James G. Mumford describes an operation which he has pr[illegible] lately [illegible] [illegible] celiac of Cheyne. Originally, as [illegible] operation consisted of: (1) Posterior [illegible] with the [illegible] of the afferent loop between the two anastomoses. As far as it goes this operation is very satisfactory, but it does not restore the parts to their normal relations. Vicious circle sometimes develops, the pylorus may resume its functions; the new gastric stoma may close. The writer ad[illegible] fourth step: (4) Section of the pylorus. Thi[illegible] risk; vicious circle is rendered impossible; the duodenum, now side-tracked, becomes a mere duct, a continuation of the common bile duct. The writer urges this operation as a routine measure, because it leaves the parts much as nature intended, and because it is easy of accomplishment.

The Etiology of Pulmonary Tuberculosis Considered in Relation to Its Therapeutics.—Louis F. High declares that there are few known pathogenic microorganisms that require such definite conditions for the maintenance of their vitality and proliferative capacity as does the bacillus tuberculosis. Various observers assert that from 50 per cent. to 98 per cent. of all persons have tuberculosis at some time of life. The mortality rate of the disease is about 15 per cent. of mankind's total death-rate, so that it at once appears that by far the larger part of those in whom it develops recover without treatment or without any directed to the real cause of the disorder. The tubercle germ has a very slight hold upon life, and can reproduce itself only under very certain and particular conditions. By experiment it has been proved that the greater number of bacilli contained in phthisical sputum and in the cavities are incapable of further growth. Investigations of the biochemistry of the bacillus and analysis of the therapeutic resources that have shown decided influence over its control, prove that the conditions for its multiplication are limited and transitory. The writer declares that he does not wish to be understood as meaning to belittle the part taken by the bacillus in its destructive rôle, nor does he incline to the relaxing in the slightest degree of any effort for the collection and destruction of phthisical sputa. No advancement made in the study of this disease, unless it be the discovery of the bacillus, so definitely points out the principal factor in its etiology, as does the success which attends the open-air treatment, when it is properly carried out. It is now admitted, although it is not generally appreciated, that the symptoms of the devitalization induced by deficient absorption and distribution of oxygen are those of incipient tuberculosis. The only difference worthy of note is the rather constant temperature phenomenon and the possibility of a slight cough in the latter disorder. So large a per cent. of recoveries follows the simple procedure of keeping patients constantly surrounded by an air supply of absolute purity, that little doubt can exist that the consequences of impure air as a result of deficient ventilation is the underlying cause of pulmonary tuberculosis. The remedy which dispels the sallow skin, pale face, [illegible] feet and hands, weak pulse, feeble power of digestion [illegible] assimilation, with the attendant loss of nerve energy, all of which are the prime characteristics of deficient oxy[illegible]enation, is the same that arrests tuberculosis when it is applied sufficiently early and continued long enough under the proper conditions. The writer concludes by saying that he believes that we should consider as a reason for the universal prevalence of this disease the incalculable extent of physical degeneration of medium degree, due to the lack of clean, pure, unbreathed outdoor air, on account of which this great scourge flourishes.

New York Medical Journal, January 28, 1905.

Preliminary Notice of a New and Simplified Double Stain for Bacillus Tuberculosis.—The method of I. S. Wile is thus described by the author: A thin smear of sputum, for example, is prepared according to ordinary methods, dried in the air, and fixed by passing three or more times through a flame. Carbol fuchsin is poured on the smear and heated to the steaming point (boiling is to be avoided) for about one minute. Thus far the technic is that ordinarily followed. Instead of using Gabbet's solution (sulphuric methyline blue) or decolorizing with acid alcohol and counterstaining with Bismarck brown, the [illegible] is drained of excess of carbol fuchsin stain, washed in distilled water, and then plunged repeatedly into Labar[illegible]que's solution until the slide presents a mottled brown [illegible]pearance. The slide is thoroughly washed in distilled water to remove any excess of hypochlorite solution, dried [illegible] between folds of filter paper, and examined with a 1-12 immersion lens. The bacilli tuberculosis appear as red rods, solid or beaded, upon a brown field. Other bacterial forms, with the possible exception of *B. smegmæ* and *B. lepræ*, are brown in color—the red having been [illegible] by the action of Labarraque's solution. *B. tuberculosis* alone retains the red stain of carbol fuchsin.

The Significance of Abulic Symptoms in Cases of Mental Diseases.—R. H. Chase defines abulia as a weakening or diminution of the will force of the individual. It may find expression in hesitation, indecision, lack of attention, [illegible] particularly noticeable in melancholia, [illegible] the depressive types of paresis; [illegible] schizophrenia, and opium and alcohol intoxication. It may be systematized, that is, present a lack of will power over [illegible] particular set or system of special acts, or general, applying at the same time to thought, action, or both, and this type is the more important. General motor abulias vary from slight hesitation of voluntary acts to extreme indecision and powerlessness. Under this general heading we may have a distinct intellectual type. In [illegible] instances a mental breakdown begins with a marked weakening of voluntary attention, and the patient soon becomes confused, restless, and eventually maniacal. In the milder conditions an aprosexia is present, as can be detected by asking the patient to read. The pronunciation of words is correct though monotonous, but when the task is finished, it is found that the patient has understood nothing that has been read. In other cases, attention is very slow and difficult to fix; when let alone, the patient indul[illegible] in silent or babbling reverie. If urged to fix the attent[illegible], the effort causes severe headache. Along with these subjective symptoms there may occur involuntary motor disturbances, and in hysterical subjects the development of new anesthesias. The exhaustion which expresses itself in headache may manifest itself also in the intelligence. A sort of crisis comes on, during which the patient appears to be in deep thought, but in reality the mental state is the reverse of that of absorbed attention. Automatic reverie is common enough in elderly persons. Moderate aprosexia may lead to merely a lack of clearness and stability in ideas; hence doubt is one of the characteristic symptoms of mental abulia. This fact explains the prevalence of obsession among the nervous and insane.

Medical News, January 28, 1905.

Some Irregular Features of Lobar Pneumonia.—Charles Knapp Law points out the sequel empyema as one of the most common irregularities of pneumonia which a physician must meet. He has found this more common in childhood and early life than in older patients. The patient generally passes the crisis as usual. The temperature may, or may not, go to normal. But the writer has never seen a case in which the pain and distress completely left the affected side. In from twenty-four hours to a week the temperature begins to rise and fluctuate, the pulse becomes weaker and more rapid, chills or chilly sensations occur, indicating the presence of pus. If, in the course of pneumonia, the resistance of the pulmonary pleura is overcome, and the germs of the disease find their entrance to the pleural cavity which is already congested and inflamed, they change a plastic or serofibrinous pleurisy to a puru-

lent one, and empyema results. The physician should never forget the possibility of the development of this complication in cases of lobar pneumonia in the young especially, and whenever the pleura is extensively involved, and the pain unusually severe and prolonged. Another irregularity of lobar pneumonia is the so-called central pneumonia, or pneumonia with late localization. The chest symptoms develop so late that in some cases the crisis is passed before a slight pleuritic friction sound is detected, which conclusively establishes the diagnosis. The extent of involvement of the lung in any case does not seem to influence the temperature. Another irregularity is called migratory pneumonia. It begins in [illegible] and while it runs its course there, extends to one or more other lobes. There may be a crisis for each lobe involved. Tympanites is a serious feature of pneumonia. It is due to a partial paralysis of the stomach and bowel, accompanied by fermentation of their contents. This condition is doubtless often aggravated by too much opiate and a too copious diet of milk. The effects are mechanical and toxic. The lungs and overworked heart are pressed upon, and the fermented intestinal products are absorbed and added to the toxemia of the disease. Unless the condition can be relieved in time, the end is without doubt fatal. The reflex pain in the initial stages of pneumonia has attracted much attention of late. It sometimes leads the physician to suspect the existence of gall-stones, peritonitis, or appendicitis. Usually, a thorough examination of the chest will reveal the existing conditions. A central pneumonia rarely gives rise to such pain. In every case of abdominal pain, the lungs should be examined, and then but few mistakes will be made.

Diagnosis of Diseases of the Upper Abdominal Region. A Plea for Earlier Surgical Interference.—C. D. Hill in speaking of this region, looks upon the stomach as the organ of greatest interest, for it is the one most apt to give rise to prominent symptoms, not only when the disease is located there, but often when the disease has its origin in another organ it affects the stomach both directly and indirectly. This special group of organs includes the pylorus, gall-bladder and ducts, pancreas, and transverse colon, all of which lie below the right lobe of the liver, and are very close one to the other. It is often very difficult to correctly localize pain or tenderness, or resistance, or even a tumor. Patients suffering with "indigestion," "stomach troubles," "liver troubles," "biliousness," and so on, are often given as many remedies as the number of physicians whom they consult. If it were realized that an accurate diagnosis is not possible, and that pathological changes of some importance are taking place in the patient's abdomen, an exploratory laparotomy would often be made to clear up the diagnosis, and it would besides be the preliminary step in relieving some mechanical condition or in removing a new growth. Of two cases of ulcer of the stomach, one will give the characteristic signs, while the other will lie dormant for years. Again, in the same patient, the symptoms vary at different periods. It is often impossible, too, to differentiate ulcer from cancer. In waiting for the classical symptoms of cancer, the opportunity for staying the progress of the disease passes by in many cases. Many investigators now believe that carcinoma of the stomach cannot be diagnosed without an exploration, at least in time to offer any relief. As to diseases of the pancreas, the diagnosis can be made only by a resort to surgery. When there exists disease of the pancreas, it is almost always secondary to disease elsewhere, especially to cholelithiasis. A short delay is sometimes grave in its results. The writer believes that a much earlier diagnosis can be made now than formerly if all of the means at our command are used. Thorough and systematic histories should be taken, noting all of the subjective symptoms, making repeated and careful physical examinations, and when practicable, using the stomach tube, and making chemical and physical examinations of the stomach contents. If after exhausting all of these methods, the diagnosis is still obscure, the time has come for surgical intervention, and surgical relief should be attempted.

American Medicine, January 28, 1905.

Feeding in Infancy.—W. P. Northrup discusses the methods of feeding a baby deprived of breast milk. The best substitute food is prepared from cow's milk from healthy herds, the milk collected clean, modified in clean surroundings, and used fresh. The laboratory method of exact modification of milk has been called the American method. Modified milk is not a patent food, but nourishment as near as possible [illegible] furnishes, and capable of being modified or changed to fit the changing needs of the infant. The proper modification can be made only by skilled persons in a proper laboratory. The cost of laboratory milk is within the reach of all who are willing to do part of the work of dividing the quart bottles of milk into separate feeding bottles. The prescriber has responsibility in feeding [illegible] The feeding of infants is an expert's work. [illegible] may serve as points of departure: [illegible] to begin after the mother's milk [illegible] per 5 per cent., proteids 0.5 per cent., [illegible] each feeding 1 oz., [illegible] for 20 minutes or raw if preferred. Feed every two hours, twice at night. (2) "Low average" breast milk: Fats 3 per cent., sugar 6 per cent., proteids 1 per cent. (3) "High average" breast milk: Fats 4 per cent., sugar 7 per cent., proteids 2 per cent.

Foreign Bodies in the Esophagus.—Carl E. Black reports two interesting cases of foreign bodies in the esophagus. The location of the foreign bodies was discovered by the Röntgen ray, and this agent was used to assist in their removal. Especial attention is called to the use of the Röntgen ray in assisting in the use of instruments under its guidance. The forceps could be introduced into the esophagus, and the foreign body grasped under fluoroscopic observation. This is of great assistance, and makes the use of the forceps or other instruments of extraction much more precise. In the first case, that of a young woman who had swallowed a pin, the bristle probang was used by several physicians, who concluded the pin was not in the esophagus, and that the symptoms were due to the irritation caused by the probang. After six days Black made an *x*-ray plate which plainly showed the pin in the esophagus, and it was removed by forceps under the direct observation of the fluoroscope. In the second case, that of a boy of 10, a 1-inch iron washer was [illegible] in the esophagus, about the level of the second rib. It could be grasped by the forceps or hook under fluoroscopic observation, but could not be dislodged. This patient died before any radical operative procedure could be undertaken.

Strabismus and Its Treatment.—C. M. Harris holds that strabismus is generally of the convergent variety, and in the vast majority of cases appears during the third and fourth years of life. These cases are as a rule monolateral and almost always associated in the deviating eye with poor vision; which may be primary or secondary to the deviation. Those occurring after five years are often of the alternating type, *i.e.* one or the other eye will fix indifferently. Good vision in both eyes is the rule, though the deformity is of course as great. Treatment should be instituted as soon as the deformity is detected, and should be carried out with patience and intelligence, or failure will result.

Journal of the American Medical Association, January 28, 1905.

Fifty Consecutive Cases of Pneumonia Without a Death.—The cases treated by W. J. Galbraith occurred in Mexico. His main reliance was upon quinine and tincture of iron. To the objection that the pneumonias were of a special type or with a malarial complication, he replies that he has never seen the latter infection in his district. The remedies named were given in large and frequent doses. In one instance 115 grains of quinine were given within a single hour. He strongly maintains that the use of alcohol and strychnine prior to resolution is harmful, as it increases the mechanical conditions distressing the patient. For controlling the nervousness and delirium of the disease he prefers bromide of lithium with chloral. He has discarded all external applications, and dresses his patients very lightly. Expectorant mixtures are seldom used except as vehicles. Syrup of liquorice and yerba santa makes an excellent vehicle for the quinine, and is also laxative. Carbonated waters should be avoided prior to resolution, as distention of the stomach interferes with respiration and embarrasses the heart. The cases referred to showed age limits of 7 and 56 years, respectively. The right lung (principally the lower lobe) was the seat of the trouble in 80 per cent. of the cases. He insists that such results as he has secured do not follow small or broken doses of the two remedies on which he pins his faith.

Chronic Arterial Hypertension.—H. W. Cook gives a general description of this condition, which he defines as an affection in which a persistent increase in arterial tension gives rise to certain symptoms, preceding the development of any discoverable organic disease, unassociated with any constant pathologic lesion, and which finally produces organic changes, particularly in the heart, blood vessels and kidneys. The most frequent pathological findings are cardiac hypertrophy and dilatation, hyperplasia of the media in the systemic arteries, thinning of the cerebral arteries, and either the arterio-sclerotic or small granular kidney. The symptoms, methods of examination, complications and diagnosis are considered in due order, and finally treatment is considered under the two headings of early and late. In early cases diet and hygiene may correct the tension. Meat should be cut down to a minimum. The great specific in the later stages is the group of nitrites, and the author considers that the nitrite of sodium has

many advantages over nitroglycerine. A single dose of from 1 to 2 grains may lower the temperature for from two to three hours, sometimes even longer. There may be a coincident very slight increase in the pulse rate with a feeling of flushing and throbbing. For a uniform, permanent effect, the remedy is best given after meals, the results then being less abrupt and most lasting. The author makes a plea for more careful measurements of vascular tension in clinical work.

The Dividing Line Between the Psychoses and Neuroses.—R. Dewey refers to the various attempts that have been made to mark out new lines in the field of psychiatry, and refers particularly to recent papers by Mercier, Dana and Runge. He himself has previously shown that a large proportion of the "neurotic" are really insane, and that "nervous prostration" is often really insanity. The phobias, obsessions, hysterias, hypochondrias, the confirmed drug and drink habits, are certainly mental as distinguished from nervous affections. It is also true that the hemiplegias, the apoplexies, the toxemias, and even the heart, kidney and arterial diseases, accompanied by disordered brain function, have insanity as a complication. Nevertheless, these cases are not generally regarded as insanities, either by the profession or the public, though technically they are such, for they are "a seriously [and persistently] impaired condition of the mental functions involving the intellect, emotions, or will, or one or more of these faculties, exclusive of temporary states produced by and accompanying acute intoxications or acute febrile diseases. The term insanity means nothing definite nowadays, as each author reads his own personal signification into it. Psychosis is a preferable word. The author thinks that recent progress in classifying nervous and mental diseases has rather been in the direction of obliterating lines than in drawing new or closer ones.

The Lancet, January 4, 1905.

Emergencies in Ophthalmic Practice.—In a lecture A. M. Ramsey calls attention to the following points: Wounds of the margins of the lids must be accurately sutured in order to prevent incision of the cilia and subsequent irritation, and also to prevent obstruction of the tear passages. In case of lacerated wounds of the lid it must be ascertained that the ball of the eye is not injured. In this class of injuries pain and distress are often out of proportion to the severity of the injury. Blepharospasm is so marked that it is imposible to separate the lids. A two per cent. cocaine solution will generally relieve this difficulty. Then an antiseptic solution can be used, followed by an ointment containing cocaine and the eye bandaged. In conjunctival burns, irrigation with a bland fluid should be followed by a five per cent. of chloretone in olive oil or cocaine in castor oil and an iced compress placed over the closed lid. In a case of sudden blows on the eyeball it is wise to adopt antiphlogistic treatment from the outset and after instilling atropine to apply leeches to the outer canthus and iced cloths to the closed eyelids, to administer a sharp purge, and to confine the patient to bed. An ophthalmoscopic examination should be made as soon as possible, so as to detect any deeper injury. A firm bandage is an essential when the injury leads to emphysema of the lids. In case of sudden blindness without a history of injury great care should be taken to immediately ascertain the condition of intraocular tension so that glaucoma may not be mistaken for some other condition and a diagnosis made of iritis. If glaucoma is determined the practitioner should at once instil eserine, to put leeches to the temples, and to apply fomentations to the eyes. If in a few hours the pain has not subsided means must be taken to reduce intraocular tension by opening the eyeball so as to relieve the strangulation at the corneoiritic angle. If the practitioner cannot obtain assistance he ought not to wait, but should at once puncture the sclerotic with a narrow knife and allow some of the vitreous to escape.

Hemorrhagic Typhoid Fever.—A case is detailed by D. Blair, his patient being an insane woman of twenty-four years, who was discovered to be passing considerable blood per rectum, with a rapid and weak pulse and high fever. The urine contained blood and there were petechial spots on the legs and arms. Later epistaxis came on with bleeding from the gums. Pulmonary consolidation ensued and the woman died on the seventh day after her symptoms were first noticed. Three diagnosis were thought possible, purpura hemorrhagia, ulcerative colitis, and latent typhoid. The autopsy revealed large, soft, and reddish inesenteric glands. The lower eighteen inches of the small intestine showed extensive ulceration of Peyer's patches and several of the ulcers had penetrated right down to the peritoneal coat. The ulcers were typical of the third stage of enteric fever and they stopped abruptly at the ileocecal valve. The spleen was acutely congested and weighed six and a half ounces. The kidneys were fairly healthy, but they, too, weighed six and a half ounces each. The disease, therefore, was obviously one of those extremely unusual types of typhoid fever exhibiting the hemorrhagic diathesis. It is extremely rare. In Ouston's 6,513 cases of typhoid fever there were only four, and in Osler's 829 cases there was only one.

A Case of Pernicious Anemia Showing Marked Improvement under Arsenic and Bone Marrow.—The patient whose history is given by J. Brunton was a woman of fifty-five years, with the typical symptoms of the disease in a marked and advanced degree. Fowler's solution was tried in small doses for a week, without noticeable benefit. Bone marrow was then added, at first in the fresh state and afterwards in the form of tablets of the marrow extract. In one month there was a marked improvement and in three months there was little in the patient's condition to show that she had been seriously ill. She remained in good condition for some six months, when pleurisy supervened and she became unable to retain arsenic in any form. The old symptoms now returned and she died three months later.

British Medical Journal, January 14, 1905.

An Address on Arteriosclerosis.—James Barr states that in the term arteriosclerosis he includes not merely the thickening of the small arteries and arterioles, but also the atheroma and calcerous degeneration which are so common in the large arteries. Arteriosclerosis is a thickening of the middle coat and an increase in the fibrous tissue of the inner coat. Long-continued straining of the arterial coats impairs the elasticity and nutrition of the vessels. The intima is nourished by inhibition, which takes place when the vessel is lax and not stretched. In high arterial tension there is no proper period of relaxation, but merely periods of greater or less distention. This constant strain leads to malnutrition of the inner coat, a chronic irritation or inflammation, which gives rise to hyperplasia of the cell elements of the subendothelial layer. This cell proliferation appears first as small white or yellowish-white patches, which soon become more yellow from fatty degeneration. True atheromatous patches soon develop. This condition may go on to ulceration or to calcification. Ulceration leads on to aneurysm. High arterial tension affects all the arteries, the arch of the aorta suffering most. As to the causes of arteriosclerosis, high blood pressure, and subsequent atheroma, it is very probable that an excessive secretion of adrenalin, especially if there be a defective action of the thyroid, may be quite sufficient to determine these conditions. Adrenalin is a vascular tonic and checks secretion from serous membranes. The secretion of the thyroid has exactly the opposite effect—it dilates the arterioles and lowers the arterial blood pressure. The part played by typhoid fever and by many other infectious processes in the induction of arteriosclerosis has been pointed out. Perhaps syphilis is the disease most often followed by disease of the arteries. Heredity has an important influence in determining arterial disease. As to treatment, the writer declares that he is very fond of agents which increase metabolism. Hence he prescribes freely the iodine compounds and thyroid. He believes that the medicine of the future will be largely one of prevention of disease and preservation of health. Physiological conditions as well as pathological ones need to be dealt with. Patients should be told not only how to get well, but how to keep well.

The Treatment of Hemoptysis.—C. H. Cattle states that in this condition, as in the case of other symptoms, the golden rule is if possible to remove the cause. Although tuberculosis is the most common cause of hemoptysis, there are other causes which should be constantly borne in mind. The accessible cavities should always be examined in all cases of doubtful origin—the nose, pharynx, larynx, and mouth. Bleeding gums should also be thought of. Many patients with bronchitis or cronchiectasis occasionally bring up a little blood-stained sputum. One form of hemoptysis depends upon degeneration of arterioles and capillaries, in gouty, rheumatic, and often emphysematous patients of middle or advanced age. The hemoptysis of heart disease can generally be distinguished by appropriate physical signs. Hemoptysis may be due to thoracic aneurysm communicating with a bronchus. When there is a brassy cough and persistent pain in the chest, this disease should always be suspected. The treatment of all these forms of hemoptysis is the same as for the symptom in general, with modifications appropriate to the disease in the course of which they occur. In the form connected with pulmonary tuberculosis, the patient should be placed at rest in bed. When the bleeding is moderate in amount, it is a good plan to give hypodermically one-quarter grain of morphine. When, however, the bleeding is so profuse as to flood the air passages, and suffocate the patient, the morphine should not be given. Free purgation is a useful measure. Calcium chloride may be given in 20 gr. doses every 4 hours. Turpentine sometimes checks internal bleeding. An ice-bag to the chest may do good by quieting the heart. Inhalation

of the nitrite of amyl may be tried. The systemic vessels are of much greater extent than the pulmonary, and thus a general dilatation of arterioles will be accompanied by diversion of blood from the pulmonary circulation and consequent reduction of pressure.

Subcutaneous Emphysema in a Case of Spasmodic Asthma.—C. J. Whitby outlines this case. The patient, a man of 25 years, had suffered since early boyhood from periodical attacks of asthma. On the second day of a recent attack the front and sides of his neck began to swell and palpation revealed the crackling of subcutaneous emphysema. This condition gradually extended up the face till it reached the lower part of the forehead, while the face and neck appeared bloated. The emphysema extended down both arms as far as the wrists, covered the front of the thorax, and extended down the back as far as the upper border of the sacrum. The attack was treated by injections of morphine, and hourly 5-minim doses of the etherial tincture of lobelia. The latter drug gave considerable relief, and the atack was terminated by the free expectoration of intensely purulent supta containing numerous pyococci, but no tubercle bacilli. After the dyspnea had been relieved, the emphysema gradually disappeared. This complication had never been noted in this patient before. He has no signs of pthisis, and his general health is good between the asthmatic attacks.

The Prolonged Use of Simple Enemata.—Charles Gaskell Higginson gives the common history of the administration of enemata in cases of long and debilitating illnesses. When the enemata are first used, the lower bowel is stimulated, and as there is great sympathy between the various parts of the alimentary canal, peristalsis from above moves the fecal contents along. But very soon toleration is progressively established in the lower gut and so on up to the upper parts of the bowel. In a few weeks, the enema ceases to stimulate and scybalæ at last form an effectual obstacle to defecation. In such a case it is well to give an enema of 10 ounces of warm olive oil at nightfall, to be retained if possible till morning. Enemata should not be used as habitual aperients. A simple enema is good for removing from below a fecal plug that is not easily moved by pressure from above, and it is good to remove feces quickly in cases in which time is an important element, as in cerebral hemorrhage. Otherwise, the writer thinks that constipation should always be treated by medicinal doses given by mouth.

Berliner klinische Wochenschrift, January 9, 1905.

Observations on Children Relative to v. Behring's Tuberculosis Theory.—Beitzke says that v. Behring's theory of tuberculous infection has so far been unsubstantiated by facts, and has rested purely on a speculative basis. According to v. Behring, only those acquire pulmonary tuberculosis who in infancy or early childhood passed through a latent infection, which may not have given rise to any external manifestations, but nevertheless produced changes in the lymphatic and vascular systems which later on rendered renewed infection easy. The author undertook to determine whether the existence of this latent form of tuberculosis in infants could be demonstrated by the detection of tubercle bacilli in the blood of cadavers which did not give any evidence of gross tuberculous lesions. The investigation was conducted by removing through a syringe as much blood from the unopened heart as could be obtained, and injecting it into guinea pigs. Ninety-eight non-tuberculous cadavers of children were available, but for various reasons the experiment could be brought to a conclusive termination on only forty-eight. Only in one case was the result of the autopsy on the guinea pigs other than absolutely negative, and in this one the doubtfulness of the result was rendered of little significance, as the subject was an infant only two days old. Control tests in six cases dying of tuberculous infections gave positive results. Jousset's methods of inoscopy was employed as a corroborative measure, but was found to be of questionable accuracy. The author concludes that his experiments, to say the least, offer nothing in favor of v. Behring's view, and that the burden of proof lies with that investigator.

Münchener medizinische Wochenschrift, January 10, 1905.

The Treatment of Tuberculosis of the Larynx With Sunlight.—Kunwald describes the very favorable results obtained in the treatment of tuberculous laryngitis by the reflection into the glottis of sunlight by means of mirrors. The patient is seated with the back to the sun, and in front of him, about the height of the mouth, an ordinary toilet dressing mirror is affixed to a suitable standard, at such an angle as to throw the light directly into the pharynx. The patient pulls forward the tongue with one hand, and with the other manipulates a laryngeal mirror in such a way as to render the image of his larynx visible in the large mirror. The best time for the treatment is early in the forenoon and late in the afternoon, as the sun's rays are more easily utilized when slanting, and it is desirable to eliminate the heat rays as much as possible. The patients soon learn the technique of the procedure and become much interested, as they are enabled to watch the improvement themselves. The length of each sitting varies from five minutes to an hour, according to the strength of the patient. The treatment is contraindicated in cases of edematous swelling of the larynx, which appear to be unfavorably influenced by the heat rays. The author gives the histories of fourteen cases in which the treatment was found of marked benefit, and he believes that improvement follows this method more rapidly than any other form of treatment.

Tuberculosis in Cold Blooded Animals.—Küster says that the results obtained by Friedmann and various other authors in attempting to immunize warm blooded animals with tubercle bacilli obtained from poikilotherms, or modified by a more or less prolonged passage through such animals, are sufficiently important to demand further investigation. He examined bacteriologically two hundred frogs and fifty other poikilotherms, and in three frogs found tubercle bacilli causing a disease similar to the tuberculosis described in other cold blooded animals. The lesion was most pronounced in the liver, which was filled with cheesy nodules. The organism grew readily on the ordinary media, with the optimum at 28° C. At 37.5° C. growth is arrested, and the cultures finally perish after the production of degeneration forms. Other cold blooded animals readily succumb to infection with the bacillus, and warm blooded animals perish after inoculation without having undergone bacillary infection in the usual sense. The author did recover the organism, however, from the body of a rat which died on the eighteenth day after inoculation, showing that a sojourn of this duration in the warm blooded animal does not suffice to kill the germ. Researches are being prosecuted in the hope of elaborating useful antibodies in the serum of experiment animals.

The Prophylactic Use of Ergot During Labor.—Prüssmann believes that postpartum atony of the uterus can be effectively guarded against by the prophylactic use of ergot, in spite of the views of those who hold that the drug should be given only after the expulsion of the placenta. He has found the hypodermatic injection of ergotin the most advantageous method of administration, and considers that the best time to give it is ten to fifteen minutes before the birth of the child. The action of the drug is less prompt in primipara than in multipara. The author recommends the prophylactic use of ergotin in this way in all operative deliveries, in multiple births, hydramnios, in deformities, and fibroid tumors, in cases of deficient pains during the first or second stages, in cases in which previous labors have been followed by hemorrhage, and in all cesarian sections. The results obtained by this plan are very satisfactory, for atonic hemorrhage was observed in only three of two hundred and ninety-three cases of forceps delivery, and only once out of one hundred and two twin labors. Fifteen cases of hydramnios, tumors or uterine deformity were delivered without atonic complications.

French and Italian Journals.

Superiority of the Organic Salts of Silver Over the Nitrate of Silver in Ocular Therapeutics.—Darier calls attention to the fact that the organic silver salts are remarkable for the large amount of silver which they contain, for their perfect solubility, their powerful antiseptic properties, their penetrating action, and finally, especially for their absolute innocuity. When placed in contact with the ocular mucosa, even in a 30 per cent. solution, they are no more irritating and no more caustic than a drop of distilled water. Used in the prophylactic treatment of purulent ophthalmia, they are in no way inferior to the nitrate of silver, and they are superior to it in that they do not cause any pain or any conjunctival irritation. In the treatment of purulent ophthalmia, they present great advantages over silver nitrate, which up to the present time has been considered the specific in this affection. Purulent ophthalmia is becoming less and less frequent, owing to the progress of obstetrical antisepsis, and many cases of conjunctivitis are not due to the gonococcus. But in all conjunctival infections due to the pneumococcus, to the streptococcus, to the bacillus of Weeks, and so on, recovery is brought about more rapidly and without pain by means of the organic silver salts.—*Le Bulletin Médical,* January 4, 1905.

A Case of Puerperal Eclampsia of Intestinal Origin.—Chambrelent reports the history of a young woman who passed through a normal pregnancy without any trace of albumin. When labor began, the breech presentation was diagnosed. Analysis of the urine was always negative. A classical eclamptic crisis occurred at the beginning of labor. Chloroform was administered, and delivery was accomplished as rapidly as possible. The urine was drawn from the bladder, but still no albumin was detected. The

evening before the labor pains began, and on the following day, the patient was in [illegible]. Chambrelent states that this is a case of eclampsia not traceable to a renal cause, but due to an intoxication of gastro-intestinal origin. The administration of a purgative was followed by the evacuation of extremely fetid stools.—*Journal de Méd. de Bordeaux,* January 1, 1905.

Internal Strangulation by Scybala.—Moty had charge of this case. Intestinal strangulation and an apparently generalized peritonitis developed, due to the presence of this mass in the sigmoid flexure. Sub-umbilical laparotomy was practised without any delay eighteen hours after the occurrence of the first violent pain in the left iliac region which ushered in the attack. The coprolith was extracted through a longitudinal incision in the colon, and the peritoneum was cleansed. The wall was sutured, leaving a place for a large subpubic drain. The patient, who was operated on December 10, is in as good condition as is possible, considering an attack of typhoid fever, and two attacks of pneumonia, from which he suffered before the intestinal trouble developed.—*Gazette des Hôpitaux Civils et Militaires,* December 31, 1904.

Examination of the Upper Pharynx by Digital Palpation Aided by Explorators.—Courtade states that digital examination of the upper pharynx is one of the most frequently employed methods for determining the existence of adenoid vegetations. It is subject, however, to various inconveniences: It cannot be used in very young children, in whom the pharynx is too small to admit the index finger; it is with difficulty that the finger can reach as far as desirable even in the adult pharynx; the exploration is of too short duration; the finger can examine only half of the pharynx, and it becomes necessary to introduce the two index fingers successively; disinfection of the hand should be rigorous, and this consumes time; finally, the examining finger is liable to be bitten. With the five explorators, the use of which the writer advocates, the pharynx can be examined without difficulty at all ages. Antisepsis is easy and rapid. The diameter of the instrument is so small that it can be passed into the narrowest throat, and as deep as may be desired. Only one exploration is necessary for a complete examination. The instrument is far more easily tolerated than the finger. Thus, if necessary, the examination can be repeated. This examination by mediate touch, practised on 150 patients, has given very valuable results.—*Le Bulletin Médical,* January 4, 1905.

Arterial Pressure in Diphtheria.—Taddei Celso has made a careful study of the conditions of blood pressure to be found in diphtheria, and gives us the following conclusions: (1) In order to give a true prognosis we should, either in pharyngeal or laryngeal diphtheria, test the blood pressure, since the changes in pressure are in direct relation to the gravity of the intoxication. (2) The behavior of the blood pressure is of the greatest importance for the prognosis in regard to complications involving the myocardium, because it indicates to what degree the heart muscle is involved, and aids in establishing the pathogenesis of the heart disturbances. (3) A marked and rapid rise of blood pressure always indicates respiratory complications. (4) In croup, before intubation, the sphygmometer continually rises, reaching its maximum just before the operation; after it the pressure gradually declines.—*Rivista di Clinica Pediatrica,* December, 1904.

Effects of Resection of the Nerves of the Pancreas.—Guiseppe Zamboni has studied the effect of cutting the nerves of the pancreas in dogs, which he kept for some time after recovery from the operation, in order to observe the effect upon the presence of glycosuria. He gives us his results. The operation was well tolerated by the dogs, and produced no important disturbances. No sugar was found in the urine, and after six months the animals had not suffered, and had gained in weight. The animals were then killed and examined. Nothing was found of any value, simply adhesions, at the site of operation. The central portion of the pancreas had been separated from its nervous connections, and had become completely atrophied. In the remainder of the gland the vessels had become much dilated, and the walls had degenerated. The parenchyma of the gland was little altered, in the islands of Langerhans there were marked regressive changes.—*La Riforma Medica,* January 7, 1905.

Two Cases of Trigeminal Neuralgia Treated by Violet Light.—F. P. Sgobbo records two cases of obstinate trigeminal neuralgia, both of long standing and severity, that had exhausted all the usual methods of treatment without permanent relief. He made applications of violet light, placing the patients in a dark room, and causing the rays to enter through a window so that only the portions of the body that were to be treated were reached by the rays. After twelve applications the pain was much relieved, and after eighteen applications and twenty-two applications respectively, the pain was entirely and permanently relieved. The author recommends the use of the violet rays in intractable cases of neuralgia as a measure of the greatest utility.—*Giornale di Elettricità Medica,* November and December, 1904.

The Paths Which Infection Takes in the Organism.—Boeri tells us that if bacteria be introduced into the subcutaneous cellular tissue they are carried into the blood by the lymphatic vessels. If they be injected into the blood current they are never obtained from the lymph of the thoracic duct. Hence, with regard to bacteria, the two circulations, blood and lymphatic, constitute two closed and distinct systems, or rather communicating from the first to the second system, and vice versa. This communication takes place at the mouth of the large lymphatic collecting vessels where they empty into the subclavian veins, and there is no communication between the two systems before this point is reached, or in the capillaries of the two systems.—*La Riforma Medica,* December 21, 1904.

Society Reports.

FOURTH PAN-AMERICAN MEDICAL CONGRESS.

Held at Panama, January 3, 4, 5, 6, and 7, 1905.

(Special Reporter to the Medical Record.)

TUESDAY, JANUARY 3—FIRST DAY.

The Fourth Pan-American Medical Congress was informally opened by a reception given by President Amador, of the Republic of Panama, at his official residence.

The formal opening took place at 8 o'clock in the evening at the National Theater. Dr. Julio Icaza, Chairman of the National Executive Committee, introduced President and Dr. AMADOR, who said:

"Ladies and Gentlemen: You have conferred a great honor upon the Government and people of this small Republic, and I feel honored in being selected by an assembly of such distinguished scientists as I see before me to preside at the opening of this Congress, which includes among its members such a number of those whom I am pleased to call my illustrious colleagues. I sincerely hope that great benefit will result from your labors, especially in considering the treatment of those diseases which have always aroused such exaggerated fear in the minds of all strangers who visit this Isthmus, that is, yellow fever and malaria. Gentlemen: I now declare open the fourth Pan-American Medical Congress."

Canal Problems.—Mr. JOHN F. WALLACE, Chief Engineer of the Canal Commission, delivered an address in which, after a brief sketch of the history of canal work on the Isthmus, prior to the American purchase, he described the condition of affairs at the present time, and told of the task which the Americans were about to take up. These problems, he said, while in an engineering way difficult, were not insurmountable. What would appear to be the most difficult and intangible one was that of sanitation, and the care and preservation of the health of the employees who were to be brought to the Isthmus for constructing the canal. To his hearers, as medical men, it might be interesting, he said, to know the general character of the labor necessary in the work on the canal. Owing to the use of modern machinery the character of the work performed by the laborer under the present plan would be vastly different from what it would have been 25 years ago; the time for digging the canal with pick and shovel had passed, and instead immense steam shovels would be used. The larger part of the laborers would be used in the construction of railroads; in general, excavation machines and apparatus would be used which would not call for the hard muscular labor which is required of the ordinary laborer. It was thought that not over 15,000 men would be needed in the construction of the canal. Possibly 10,000 of these men would be common laborers; possibly 2,000 to 2,500 would be laborers requiring some skill. Of these 10,000 men, practically all would be natives of the towns and country adjacent, unless it was found necessary to bring labor from China and Japan to supplement the force which could not be

obtained on the Isthmus. Some 4,000 men would be skilled mechanics. Possibly 1,000 educated Americans would be required as engineers, clerks, etc. These figures were only approximate, as it was difficult to determine the character and the actual number of men who would be needed, as the plans had not yet been determined in all of their detail, and the machinery to be used had not been selected. The task of preserving the health of this army of men was now in the hands of Colonel Gorgas, and the success of this work would largely be due to his efforts and those of his Department.

Earlier Conditions of the Canal.—Mr. Tracy Robinson, one of the residents of the Isthmus, delivered an address on this subject. He said he would go back a little to the opening of the Panama Railroad on January 31, 1855. This, next to the discovery of the Pacific by Balboa, was the most important event that had occurred on Isthmian soil. The last rail was laid at Culebra in a dark, rainy night, after incredible vicissitudes of labor, sickness, poverty, and lack of confidence; but now for 50 years trains of passengers and merchandise had passed with regularity and safety from ocean to ocean.

Canal talk had always been in the air. In 1869, General Grant sent General Hurlbut to Bogotá charged with power to make a canal treaty, but before it could be ratified by the United States Senate, it was so modified by the Colombian Congress as to kill it. The French work on the canal had proved a curse rather than a blessing to the inhabitants of the Isthmus. A fatal drawback had been the instability of the Government in which there was a revolution about every year. On November 3, 1903, the Republic of Panama was proclaimed, and hope was now once more alive. Great things were expected, Mr. Robinson said, from the influence of the medical profession on the new canal project. The speaker joined his Panama brethren in extending the hand of welcome to the members of the Congress. They could at least draw upon the residents' fund of daily experience. They would learn how false were tales of danger and death from the Panama climate. There never had been a real epidemic of yellow fever on the Isthmus for 50 years; many had died of the fever, it was true, but there had never been an epidemic. All the members of the Sanitary Corps of the Canal Commission were up-to-date medical men—true missionaries. To them all looked for health and strength. The trained physician always led, and he could be the captain in the battle of scientific civilization against bigotry and ignorance.

Dr. José E. Calvo, Secretary General of the Congress, said that it was his duty to give all information and attend to the business of the Congress. The third meeting of the Pan-American Medical Congress took place in 1901 in Havana. This fourth Congress was now to be held here; only a few days after that third of November when Panama secured her independence under the leadership of Dr. Amador, the country through Don Tomás Airais accepted the invitation of the American Minister to hold the Congress in Panama, and the residents extended to all members of the Congress the hospitality of their modest city and wished them to become their guests. If they had not the charm of large cities, they still took great pride in the visit of so many distinguished physicians, and hoped that they would be rewarded for having come so far. He announced that Mexico, Guatemala, the United States of America, Honduras, Santo Domingo, Cuba, Peru, and Porto Rico had sent official delegates, and so also had the Medical Faculty of Costa Rica and the Academy of Sciences of Havana. About 200 members were expected from the United States. Eighty-six papers had been received and the speaker assured all present that everything within the power of the physicians of Panama to make the Congress a success would be done.

Sanitary Conditions as Encountered in Cuba and Panama and What Is Being Done to Render the Canal Zone Healthy.—Colonel W. C. Gorgas, Chief Sanitary Officer of the Isthmian Canal Commission, delivered an address with this title. (See page 161.)

Wednesday, January 4—Second Day.

The morning was spent in an informal excursion to the Savanas, a suburb where there are several country houses. The guests were entertained at luncheon by Dr. Icaza.

The scientific session was held at 3 o'clock in the National Theater, Dr. Carter of the U. S. Public Health and Marine Hospital Service presiding.

A New Method of Incising and Suturing the Liver to Reestablish Its Continuity and for the Control of Hemorrhage.—Dr. Jacob Frank of Chicago, read this paper. He said that all modern surgery, especially abdominal surgery, sought to secure primary union, thus minimizing infection and hernia; this principle should be applicable to surgery of the liver provided proper technique were employed. If the surfaces were properly coapted the continuity would be reestablished, primary union secured, and hemorrhage prevented. Injuries of the liver had always been considered grave, and those of the concave surface more dangerous than those of the convex. Compression had been now usually tried to stop hemorrhage. Elliott maintained that that was the only method. Dr. Frank described five procedures (1) packing the wound and fixing the stump intraperitoneally; (2) packing, and dropping the stump into the abdominal cavity; (3) application of the thermocautery to the stump and packing; (4) suturing and packing; (5) suture alone. Besides this the stump might be ligated en masse or the tourniquet might be tried. It was now pretty well proven that hemorrhage could be controlled by suture, catgut being preferred to silk. The speaker had lately experimented on dogs, making deep incisions into or through the liver; some recovered without any treatment whatever. Then he excised a wedge-shaped piece from the liver securing exact apposition (this he considered essential), securing the bleeding vessels by ligature. The edges were then held in contact and sutured by catgut. The results were surprisingly good. This method was particularly applicable to tumors, for they usually appeared at the edge of the liver. The incision must be free so as to be sure to remove the growth completely.

Dr. Nicholas Senn, of Chicago, said he congratulated the Congress on having listened to this original paper. He suggested, however, that these experiments were made on normal tissue and that the conditions were not necessarily such as would be found in pathological tissue. In cases calling for surgical interference the chance of hemorrhage was greater because the vascular channels were enlarged. Surgery must imitate nature. Now the retraction of the cut ends of blood vessels was a mechanical impossibility in the parenchyma of the liver. A thrombus was the only thing really to be trusted to arrest liver hemorrhage. Nature would provide a thrombus when the liver was torn or lacerated. Why not then use a dull instrument, a dull knife, a wire or chain to cut the liver? The idea of excising the wedge of tissue was excellent.

Dr. George Crile of Cleveland said that the venous circulation of the liver was low and that even pressure was necessary to continue it. He thought that on this account hemorrhage would be checked by Dr. Frank's method of suture.

Dr. Frank, in closing, said that he had not found that crushing of the liver tissue would stop bleeding; in fact, it was this very tissue that kept on bleeding. He thought that to remove crushed tissue and to get accurate approximation was the best way to stop hemorrhage and to secure primary union. He had lately received reports concerning gall-bladder surgery in which the operator had found that after removal of the gall-bladder, hemorrhage from the liver was best controlled by suture. In operating on man, it was best to operate quickly; and to control the blood or else to prevent it from entering the peritoneal cavity.

Surgical Physiology.—Dr. George Crile of Cleveland read a paper on this subject. Surgery, he said, had passed

out of the empirical stage; it had learned its lessons from anatomy, histology, and pathology, and even from bacteriology; but we still had many lessons to learn from surgical physiology. We knew little or nothing of the physiological alterations leading up to death or to recovery, or of the method of compensation in injury or disease, or of local and general resistance against infection. Surgical practice rested largely upon altered physiological actions. Good illustrations of this point were found in the surgical physiology of the two most vital phenomena, respiration and circulation. In respiratory obstruction respirations were not immediately arrested, but were stimulated in force though not in frequency; in mechanical stimulation of the laryngeal mucosa, there was usually an immediate respiratory arrest; therefore, there should not be a moment of doubt in differentiating between reflex inhibition and obstruction, thus avoiding certain crises in the extraction of foreign bodies or in performing intubation. In administering anesthetics the student must remember that if the tongue were pulled forward too forcibly respiration would be arrested. The better way was to remember also the increased respiratory action caused by divulsion of the anus and to call upon the accessory muscular apparatus to help respiration. The surgical physiology of the circulation was more vital than that of the respiration. The control of the circulation often meant control of life itself. If by any reflex action the vasomotor system was disturbed, its function was impaired and the blood pressure fell. If the surgeon remembered this he would guard against excessive manipulation and would try to support the circulation by such mechanical means as saline infusions, posture, or bandaging. All knew that a hard pulse and high blood pressure were characteristic of increased intracranial pressure. This might lead the surgeon into a feeling of false security. Chloroform should not be pushed to full anesthesia; if it was, the blood pressure was apt to fall and cause a sudden arrest of respiration and circulation. The heart might be inhibited from mechanical stimulation of the trunk of the superior laryngeal nerve in operations upon the larynx, and death might occur, although it should not. Again, a blow upon the lower ribs or pit of the stomach did not cause collapse or death from disturbance of the solar plexus, but from inhibition of the heart. These were only a few of the problems offered by surgical physiology. Another was that of suspended animation. The different parts of the body had varying periods of suspended animation, and death fell unevenly on the different tissues and organs. He had been able to resuscitate a dog fifteen minutes after complete stoppage of respiration and circulation, that is, apparent death. A decapitated dog had been kept alive for twelve hours by continuous slow infusion of a 1-15,000 solution of adrenalin in salt solution. Other experiments were reported. The great lesson to be learned was that physiology must be studied carefully to benefit surgery.

Dr. Martinez of Havana had seen cases of inhibition of respiration after thyroidectomy. He believed inhibition was more reflex than mechanical.

Dr. Crile agreed with Martinez about reflex inhibition. It was hard to kill the patient if the heart was kept nourished by inversion, thoracic compression, etc.

Some Gynecological Superstitions.—Dr. Lucy Waite of Chicago read a paper with this title, in which she said these superstitions were hard to overthrow. The first was that the uterus had any normal position; it had not; it might lie in any position. The second was that retrodeviation was the cause of constipation; that was not so, and it could not be proved either by dissection or examination. She had had five hundred cases analyzed but could not trace constipation to posture of the uterus alone. The uterus was found in anteroposition in 60 per cent., in retroposition in 40 per cent. Of the anteropositions 52 per cent. gave a history of constipation, 48 per cent. did not. Of the retropositions 66 per cent. complained of chronic constipation and 33 per cent. had normal bowel movements.. The third was that backache was a symptom of retrodeviation; this was nonsense, and an examination by the speaker of one thousand cases had disproved that superstition. The fourth was that flexion or stenosis was the cause of dysmenorrhea; this was not so nor was childbirth the only cure. Of 300 cases in which the question was asked: "Have you had more or less pain since the birth of your children?" the answer of 135 was more pain, of 89 less pain, of 76 no difference. Some of these 76 had had no pain before or since childbearing. Of the 135 some had had no pain before childbearing. Many women had suffered worse after childbirth than before. The mania for operating ought to be checked on the death of these superstitions.

Dr. Crile of Cleveland quoted Head's results in the study of referred pain. He asked Dr. Waite whether all backaches were attributed to the uterus and whether backaches were often accompanied by leg aches.

Dr. Waite, in closing, said that not all backaches were traceable as referred pains to the uterus but that there was usually some pelvic disturbance rather than any malposition of the uterus.

Extraction of Cataract.—Dr. S. D. Risley of Philadelphia read a paper on the choice of operation for cataract based upon intraocular conditions. He said the purpose of the paper was to set forth the technique of extraction based upon certain complicating conditions, their relation to the opaque lens, and the extent to which the complications modified prognosis and rendered the removal of cataract difficult and dangerous. The cataractous eye was to be regarded as not free from disease. The term senile cataract was misleading, since it removed hard cataract from the domain of pathology and placed it like gray hair among the signs of advanced life. The only difference was that the lens was soft in early life, hard in advanced life; but cataract occurred comparatively rarely in the aged and there was no relation between it and the signs of general senility. In any study of cataracts, it would be found that early there were asthenopic symptoms, swollen and red caruncles, thickening of retrotarsal folds, and headache; as cataract matured and reading was abandoned, these diminished. There might also be found during the incipient stage anomalies of refraction and some fundus changes; sometimes fluidity of the vitreous. There was an obvious relation between choroidal disease, eye strain, and lens opacity; also between the lens opacity and the gouty or rheumatic diathesis. The blood-vessels of the retina and choroid were prone to participate in disease of the general vascular system. The nutrition of the eyeball was dependent upon the circulation of the uveal track. Vitreous and lens were apt to suffer as well as the posterior capsule; therefore, it was best not to operate in the immature stage, *i.e.* until the morbid process had ceased to progress. The speaker never attemped operation in the case of a dull gray or amber-colored lens that had ripened slowly or of one that was translucent; when the iris lacked luster and did not dilate easily it was liable to traumatic iritis. It was best to treat such cases by iodides and bromides internally and by some mydriatic, and to perform a preliminary iridectomy from four to six weeks in advance, using cocaine if possible. If the lens was extracted in the capsule, Risley preferred a Kalt stitch through the cornea with a large corneal section; then a wire loop was introduced and the lens delivered by gentle traction. In anterior capsulotomy, the danger was less and the corneal section might be smaller, but a secondary operation was usually necessary; for this, he preferred two knives (of his own device) introduced at the same time. He preferred a light firm bandage with confinement in bed as short a time as possible. A mydriatic and the salicylates were generally useful.

The Banquet.—The evening was taken up by an elaborate banquet at the Hotel Central, presided over by the President of the Republic of Panama, the Bishop of Panama, and the Secretary of State. Many congratulatory speeches were made. The pleasure, however, was dampened by fear for the steamer *Athos,* which was thought to have left Baltimore

in time to reach Colon Tuesday morning, but up to the hour of the banquet no news had been heard from her. She was especially chartered for this occasion and carried nearly fifty delegates whose presence was greatly missed both socially and scientifically.

(To be Continued.)

THE PRACTITIONERS' SOCIETY OF NEW YORK.

192d Regular Meeting, Held January 9, 1905

The President, Dr. Charles Stedman Bull, in the Chair.

Intramuscular Hemorrhage from Muscular Action. Dr. Andrew H. Smith read this paper (see page 193).

Dr. Robert Abbe said the condition described by Dr. Smith was of interest in connection with cases of which he had seen several examples, in which a permanent tumor appeared after injury or muscular section. In the cases he has observed, these tumors proved, upon investigation, to be nothing more than the muscle-ends. He recalled the case of a military man who, after a long horseback ride, developed a mass as large as an adult fist on the upper, inner aspect of the thigh. This mass was permanent, and was evidently due to a rupture of the adductor muscles from the bone, with subsequent retraction. Dr. Abbe recalled another case in which the biceps was torn through its lower end, resulting in one of these muscular tumors, although the patient still had good use of the arm. In connection with the sternocleidomastoid muscle the condition was occasionally observed in infants. In those cases it was probably due to separation of part of the muscle at birth from tension, and it had been suggested that this was the explanation of the commencement of many cases of congenital wry-neck. Dr. Abbe said he had seen two interesting examples of this condition in the leg, which had first been brought to his notice by the French writers under the name of *"coup de fouet"* or "whip-snap." One of the patients was a woman who met with this accident while stepping from her carriage, and she was disabled for many weeks. In the other instance the injury occurred to a man who leaped over a ditch. His recovery was tedious, and there was a great deal of pain. As regarded the composition of these tumors, Dr. Abbe thought they were largely composed of muscular tissue, and that the hematocele element was of secondary importance. As regarded treatment, the speaker preferred putting the muscle at rest. He was not an advocate of massage in treating this class of injuries.

Dr. George L. Peabody thought the accident described by Dr. Smith was comparatively rare. He recalled one that came under his observation some years ago. The patient was a middle-aged lady who was visiting in Newport. She was not accustomed to a polished-wood floor in her bedroom, and in getting out of bed in the morning, the rug upon which she stepped slipped from under her feet. She made a violent effort to save herself from falling, and in doing so experienced a sharp pain in the upper abdominal wall, a little to the right of the median line. This was so severe that she had to remain in bed. Subsequently, an ecchymosis developed at the site of the pain. There was no tumefaction, but it was many weeks before the tenderness and pain disappeared. When this condition was met with in the extremities, Dr. Peabody said, unless there was distinct tumefaction or an hematocele, the possibility of pain and edema being caused by an embolus should never be lost sight of. Embolism affecting one of the peripheral arteries was attended by great pain and sometimes by edema, but of course this condition could be ruled out in an otherwise healthy subject.

Dr. Abbe recalled a case similar to the one reported by Dr. Peabody. The patient was a gentleman who was riding in a Broadway car. The car stopped suddenly, throwing the man forward. When Dr. Abbe first saw him some weeks afterwards, he had what was supposed to be a rupture of the abdominal wall, with a hernia of the intestine. Inspection showed a sulcus in which the finger could be placed. This proved to be due to a rupture of the right rectus muscle, which was torn away and formed a tumor not unlike a hernia.

Dr. Andrew H. Smith, in reply to a question as to whether these intramuscular hemorrhages ever occurred independent of a rupture of the muscular fibres, said he supposed that would be possible under certain conditions. An actual rupture of the muscular tissue, however, with resulting hemorrhage, was more likely to occur. As regarded the age at which this accident was most common, Dr. Smith said that in most of the cases cited in literature, the patients were past middle life, but there was no evidence, so far as he knew, that the blood-vessels were in any way impaired.

Dr. Hermann M. Biggs said he had seen one or two cases similar to those described by Dr. Smith. One was that of a man, about 52 or 54 years old, who in stepping off a car experienced a sharp pain in the calf of the leg. When Dr. Biggs saw him, a few hours later, there were distinct evidences of an intramuscular hemorrhage. There was a large tumor, which subsequently became ecchymotic, and it was a number of weeks before recovery occurred. In the cases that had come under his observation, the speaker said he had always been inclined to believe that the blood-vessels were diseased, or, in other words, that such a rupture was not apt to occur in normal tissue.

Dr. Beverley Robinson referred to the clay mixtures that were in vogue years ago as external applications to allay inflammation, and said it would be interesting to learn why they had fallen into disuse. He also raised the query whether massage was contraindicated in cases of deep-seated pain, with tumefaction, and the possibility of a small pus focus.

Dr. Andrew H. Smith said the calf of the leg presented peculiar anatomical conditions, which rendered it particularly liable to this form of lesion. The muscles in this region were inclosed in a non-elastic, non-distensible fascia; the muscular bundle completely filled this fascia and was cut up by intermuscular septa, so that it could be regarded as one great sac or a number of small sacs, each one containing its own muscle, and all involved in one common investment. With even a small amount of blood extravasated into such a confined space we were apt to get more or less the action of an hydraulic press, and a single cubic inch of blood effused under those conditions might create a great deal of disturbance. Dr. Smith asked Dr. Abbe whether, under the conditions he had described, it would not be good surgery to lay open the blood sac freely, or at least to make an incision large enough to permit its contents to escape?

Dr. Abbe said that, in view of the freedom with which the knife could be used to-day, he thought it would be entirely safe and justifiable to relieve the tension by making such an incision as seemed necessary. In reply to the question whether it was ever advisable to dissipate small quantities of pus by massage, Dr. Abbe replied that to attempt such treatment was contrary to surgical principles. Nature usually established a barrier to keep pus collections confined, and in such cases the knife was safer treatment than massage and more efficacious.

Dr. Andrew H. Smith said that while massage had been generally recommended in the treatment of this condition, especially when a good deal of blood had escaped, he did not favor its use in the early stage. In his own cases, massage rendered the patients more comfortable for the time being, but it appeared to aggravate the symptoms afterward. In none of the cases reported was there any temperature disturbance, or anything to lead to the belief that there was pus formation.

Treatment of Superficial Pain.—Dr. Beverley Robinson reported the case of a young man who complained of pain in the right arm in connection with certain movements of the extremity. The pain was worse at night, and seemed to be partly neuralgic, partly neuritic. There was

no constitutional disturbance. Various local applications were tried without much resulting benefit. The pain disappeared, however, under the use of the electric pad applied in connection with a moist bandage. It was found that moist heat proved far more efficacious than dry heat.

Dr. Peabody said that in the treatment of these superficial pains he had seen much benefit follow the use of alcohol applications. About half a dozen layers of cheese-cloth were impregnated with alcohol and kept in contact with the skin for hours. Sometimes he covered the cheese-cloth with an impervious rubber-tissue dressing. By this method, he had relieved superficial neuralgic and neuritic pains, and even those due to phlebitis. Alcohol was very volatile; it was absorbed to a certain extent, and produced a local paralysis and therefore dilatation of the blood vessels, and in this way probably increased the activity of the circulation locally. In only one instance, Dr. Peabody said, had he seen this application result in harm. In that case the patient was the wife of a surgeon. She had a rather severe coxalgia, to which the alcohol was applied in the usual manner. The impervious dressing covering the cheese-cloth, however, was applied too hermetically, and a superficial slough over the coccyx resulted, which was rather slow in healing. In regions where the epidermis was very thin, for example, over the scrotum, the alcohol should be applied with great caution, if at all.

Some Unusual Features Observed in the Recent Outbreak of Typhoid Fever.—Dr. A. Alexander Smith said that during his hospital service last autumn he was very much struck by some unusual features observed in the course of his cases of typhoid fever. The first of these was in connection with the temperature, the variability of which was very marked. In some of the early cases, without any treatment whatever, the temperature would go down to normal, or nearly so, remain thus for a day or two, and then again go up. This unusual variability occurred in many of the cases under observation, and was apparently entirely independent of treatment. It was not exceptional to see a temperature of 103° suddenly drop to normal, remain so for two days, and then rise again. Another unusual feature of the temperature was its rapid decline. In a large proportion of the cases, it was almost by crisis, without hemorrhage or any other feature to account for it.

Out of 35 cases of typhoid fever recently observed by Dr. Smith, bronchitis was a prominent feature in thirteen. This was an unusually large proportion. Two of the patients had been sent to the hospital from the dispensary with the diagnosis of probable acute tuberculosis, because of the pulmonary symptoms and the high temperature. Only after careful investigation and making every possible test was it determined that the patients were suffering from early typhoid fever in connection with a severe bronchitis. Another unusual feature of his series of cases was the number of relapses. Out of thirty-five cases, ten had relapses. Dr. Smith said this was the highest percentage of relapses he had ever observed. In two of the cases there were two relapses. In four of the cases there were intestinal hemorrhages—also a large proportion. Another unusual feature was that the Widal reaction was only obtained very late in the course of the disease. The earliest it was observed was on the fourteenth day, and there were cases in which repeated examinations of the blood gave no reaction.

Dr. Smith said he had learned to have great confidence in the leucocyte count in cases of continued fever. In one of the cases, where the leucocyte count was 17,000, the patient died, and at the autopsy, enormous ulcers were found throughout the ileum and colon. The mortality of his 35 cases was two per cent. One of the fatal cases had a perforation, and was moribund when brought to the hospital. The other fatal case was the one with the numerous ulcers. In many of the cases blood cultures were made, but only two showed anything positive.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Stated Meeting, Held January 31, February 1 and 2, 1905.

The President, Dr. Hamilton D. Wey of Elmira in the Chair

(Special Report to the Medical Record.)

First Day, January 31, 1905.

The ninety-ninth annual meeting of this Society was held in the Common Council Chamber, City Hall, Albany, New York. The proceedings were opened with prayer by the Rev. T. St. George McLean, Rector of Trinity Church, Albany.

President's Inaugural Address.—Dr. Hamilton D. Wey of Elmira said that whatever of success attached to this meeting was to be credited to loyal, devoted and self-sacrificing members of this society imbued with its traditions and solicitous for its welfare. He said that the report of the Joint Committee of Conference representing the Medical Society of the State of New York and the New York State Medical Association, appointed to facilitate and expedite the unification of the medical profession of this State, merited their earnest, thoughtful consideration. He said the recommendations carried with the report should receive their adoption and indorsement. One year ago it was confidently expected that at this meeting existing medical division would be obliterated, the differences and dissensions of former years would become as the indistinctness of a dream, and the profession united and unified to consider the higher problem of the hour and day without the distraction of academic discussions. The objections based upon legal grounds and conceded by counsel to be good and sufficient, acted as an estoppel and prevented the Association proceeding at that time with the merger. It was the intention at the present meeting to correct errors of procedure so that what might be done in the future would be unquestioned from a legal standpoint. Reference was made to the State Hospital for the treatment of incipient pulmonary tuberculosis at Ray Brook, Essex County. He hoped the results obtained would serve an educational purpose in directing public attention to the importance of the early treatment of pulmonary tuberculosis, and the amenability of the disease during its initial period to appropriate measures. He said that approximately 10 per cent. of the yearly mortality in this State was occasioned by this disease, from 13,000 to 14,000 lives being annually lost from this cause alone. He said that next year would occur the one hundredth annual meeting of this society, and it was incumbent upon them that it should be observed and celebrated in fitting and appropriate manner. According to the *Transactions* for 1904 it was stated eight counties were not in affiliation with and represented in the society. It was the duty of the State society to strengthen local societies having representation, so far as lay in its power. He believed the present to be a favorable time for the abolition of the delegate system, and recommended eligibility for membership of all members in good standing of county societies. Since the last meeting there had passed beyond three honorary and eleven permanent members. After welcoming all, he declared the ninety-ninth meeting open for business.

Report of Committee on Conference.—Dr. H. L. Elsner of Syracuse, chairman of this committee, reviewed the work done towards amalgamation since January, 1902, and the progress that had been made. It was interesting to note that there were 694 active members of the county medical associations and 6,655 of the county medical societies desirous of amalgamation, making a total of 7,349 active members from both bodies, leaving but 77 members of the association who failed to ratify the agreement. If amalgamation was effected it recommended that there be a clear title, without a single flaw, and that it should rest upon a firm foundation; therefore, they indorsed the recommendation of the president that the delegate system be abolished,

and all members in good standing in their respective societies be admitted to membership.

The following resolution was then offered by Dr. D. B. St. John Roosa of New York, and passed unanimously: That the Committee of the Society heretofore appointed for the purpose of bringing about consolidation, namely, Drs. Henry L. Elsner, Abraham Jacobi, Albert Vanderveer, George Ryerson Fowler, and Frank Van Fleet be and they are continued as such committee with full power and authority to do whatever may be necessary to carry the agreement into effect.

Committee on Hygiene.—Dr. JOHN L. HEFFRON of Syracuse, chairman of this committee, reported that they advised some national law to be passed to provide for the procuring of pure food. Also, because wood alcohol was being so much used in blending alcoholic beverages, they recommended that the society attempt to secure the passage of a law forbidding this practise, and that if the law was violated the same penalty should be inflicted as for manslaughter. With regard to railway sanitation, they recommended that the governor appoint a committee whose duty it would be to see that proper sanitary measures were carried out on cars at both ends of runs.

Report of Committee of State Board of Medical Examiners.—Dr. LEWI reported the total number of candidates for license since the board was established, 8,583; of these there were successful 6,828, or 79.5 per cent.; unsuccessful, 1,755, or 20 per cent. The total number of candidates from July 31, 1903, to August 1, 1904, was 922; appearing for full license, 471; successful, 360; unsuccessful, 111. There had appeared before the Homeopathic board, 223; successful, 21; unsuccessful, 2. There had appeared before the Eclectic board, 21; successful, 12; unsuccessful, 9. The men who were elected to serve until August 1, 1906, were Dr. William Warren Potter, president; Dr. M. J. Lewi, secretary.

Report of Treasurer.—Dr. O. D. BALL of Albany reported that the amount on hand was $2,707.52.

Dermatitis Seborrhoica and Its Relation to Alopecia, and Other Conditions.—Dr. L. DUNCAN BULKLEY of New York read this paper, and gave his clinical experience with the disease and a study of its true character, giving an analysis of 755 cases of dermatitis seborrhoica and 608 cases of alopecia. He also referred to its simulation to other conditions, such as psoriasis, pitiriasis rosea and ringworm. Alopecia he considered to be of parasitic origin, although the microorganism causing the disease had not yet been agreed upon by most observers. In the treatment of dermatitis seborrhoica he stated that most writers laid great stress upon the local treatment. The internal treatment had relatively little direct influence upon the eruption; there was no internal specific for the disease yet known. More attention should be paid to diet, and such internal medication along the lines as laid down in the treatment for eczema. There were many variations in the local treatment. If the scalp was involved lotions were better than ointments, and the one he preferred was composed of resorcin, alcohol, glycerin, and rose water. In some cases equal parts of resorcin and chloral hydrate gave better results than when resorcin was employed alone. Dermatitis seborrhoica made up one-tenth of all the cases that consulted the dermatologist. The condition was often mistaken for eczema, psoriasis, etc.

Dr. RALPH A. MCDONNELL of New Haven, Conn., said that it was utterly impossible to cure cases of acne rosacea or vulgaris without removing from the dietary such substances which were digested in the upper digestive tract, and which caused intestinal fermentation. In cases of incipient baldness advance should be made along the line of internal treatment if good results were to be had.

To What Extent are Cycloplegics Necessary in Determining the Refraction of the Eye and in the Prescribing of Lenses.—Dr. FRANK VAN FLEET of New York read this paper. In considering this subject he said it was necessary to know just what the conditions were that required the use of glasses, and what we expected to accomplish by their aid. He confined himself to the refraction of the eye including the ciliary muscle, on which depended, so he believed, the determination of the whole subject. He then considered the eye as an optical organ and, again, as an organ of vision. The eye being an active organ, a part of an active system, one could not eliminate one part and retain the normal sequence. So he believed that if one paralyzed the ciliary muscle when attempts were made to correct the defects of the eye with lenses, you were starting from an erroneous base, by placing the eye in an abnormal condition. There was no way in which one could determine the nature of the condition which you had to deal with from the character of the symptoms presented. Headaches were generally considered to result from hypermetropia and astigmatism rather than from myopia, yet there were many exceptions. It should be borne in mind that it was not a positive indication that glasses were not properly fitted because the symptoms for which they were prescribed, and which seemed to be referable to the eye, did not cease when the lenses were worn. He thought it would be admitted that cycloplegics were not necessary in making an ophthalmoscopic examination. If one desired to dilate the pupil for this purpose, cocaine could be used. Cycloplegics were used to allow one to estimate the amount of error. The bright light of the ophthalmoscopic mirror, thrown into the eye, at first caused a contraction of the pupil, which was followed by a dilatation of the iris and an accompanying relaxation of the ciliary muscle; and this, in the majority of the cases, was sufficient to enable one to estimate the amount of error, especially in hypermetropia, with sufficient accuracy for all practical purposes, and if one desired you could find that this was confirmed by examination under atropine. In determining the lens to prescribe in hypermetropia with asthenopic symptoms his plan was to correct the amount of manifest error and increase the strength of the lens as circumstances necessitated. To a person with asthenopia, who had never worn glasses, the correction of manifest hypermetropia would give relief and comfort. If the necessary relief was not obtained, or if the patient would not accept the lens, he believed a cycloplegic should be resorted to. What he said regarding hypermetropia applied to astigmatism, with certain modifications. Observations had demonstrated that astigmatism was generally corneal, and also that a certain amount of lenticular astigmatism was normal. He believed that, as a rule, in simple hypermetropia and in hypermetropic astigmatism it was only the amount which was uncompensated for, or which was compensated for with difficulty, and if this was corrected the trouble would cease. In simple myopic astigmatism the patient would generally accept the glass which represented the full amount of the error; whereas, in simple hypermetropic astigmatism this might or might not be the case. In mixed astigmatism he often used atropine. Extended experience tended to confirm the belief that children of tender years, afflicted with myopia, should have their accommodation paralyzed with atropine at least every six months, the eyes being protected with colored glasses, until you were confident that the tendency of the disease was not to increase. In children with intermittent strabismus convergence atropine would procure good results. In older people who had gone through years of agony from uncorrected eye-strain atropine would accomplish a great deal by enforcing rest. He believed that cycloplegics should be used but exceptionally in the refraction room.

Rheumatism and the Eye Muscles.—Dr. FRANCIS VALK of New York read this paper, and stated that the uric acid diathesis might affect the ocular muscles, not a paresis, producing certain symptoms similar to those of muscular asthenopia. These symptoms could only be shown by the findings of the tests for the muscular rotation of the eyeballs under fusion and version, the latter by turning the eye under the influence of the will, which test was somewhat

crude. In the uric acid diathesis one or both fields might be restricted in all directions of rotation of the eye. He then related two interesting cases.

Dr. A. Edward Davis of New York discussed the paper.

The Simulation of Appendicitis by Cholelithiasis.—Dr. Geo. G. Lempe of Albany read this paper.

Arteriosclerosis Affecting the Nervous System.—Dr. B. C. Loveland of Syracuse contributed this paper, and said that his attention had first been called to this subject ten or twelve years ago by Dr. Starr. The toxic etiology was admitted by all. Excessive exercise, mental or physical, was thought to be a cause by some. The ingestion of food, tobacco and tea predisposed to the condition. He then entered into detail as to how arteriosclerosis affected the cerebral, spinal, peripheral, and sympathetic parts of the nervous system. An early diagnosis was of the utmost importance. Disordered function of the brain, heart, kidneys, and other organs should be considered before they became irreparably injured. The waste of the body should be minimized in order not to burden the circulation. Any strain, mental or physical, especially which required the use of stimulants, should be avoided. Several hours' sleep should be insisted upon. Among the remedies used, the iodides have the lead, especially the yellow iodide of mercury, which never seemed to disturb the stomach. Aconite in large doses, given for several months, was recommended by Thomson. Strychnine might be used when indicated without changing arterial tension. The mechanical and electrical treatment each had their place.

Loss of Vision from Disuse of the Eye, Amblyopia ex Anopsia.—Dr. D. B. St. John Roosa of New York read this paper. (To be published later.)

Drs. Frank Van Fleet of New York, Howe of B[illegible], Valk of New York, and Davis of New York discussed the paper.

Biliary Drainage in Operations on the Gall Bladder and Biliary Ducts.—Dr. Eugene A. Smith of Buffalo read this paper. He emphasized the importance of draining the biliary tracts in operations upon the gall-bladder and the ducts. He referred briefly to twenty-five operations he had performed, in which he had drained the gall-bladder and biliary ducts twenty times. It was interesting to note that in some cases the discharge of bile was excessive, sixteen to thirty ounces occurring in twenty-four hours during the first week. The hepatic function was restored partly or completely according as he was able to correct the pathological process. Cholecystectomy without drainage must be guardedly advised. Drainage in cholecystectomy was perfect, although it was stated by some that as the result of a prolonged fistula cure might only be obtained by resorting to cholecystectomy; that had not been his experience. In his series of twenty-five operations there had been but two deaths. Acute pyogenic infection demanded drainage at once.

Report of a Case of Vasomotor Disturbance Caused by Exposure to Sunlight.—Dr. Samuel B. Ward of Albany reported a case of erythema and urticaria, with a condition resembling angioneurotic edema caused only by exposure to the sun's rays. There was no purpura. There had been a history of muscular rheumatism for some years previous. There were digestive disturbances with much formation of gas, but no colics; there was no history of nephritis.

Dr. E. Wood Ruggles of Rochester, Dr. Kinnear and Dr. F. C. Curtis of Albany discussed this paper.

Pathology and Bacteriology.—Dr. W. T. Councilman of Boston said that the pia mater was a more or less lymphatic in nature. Strictly speaking all cases of meningitis deserved the term meningo-encephalitis because of the intimate connection between the blood vessels and the lymph channels. Infectious agents might gain access by way of the blood or from an extension from some foci of infection by means of the lymphatics. All cases of meningitis were really cerebrospinal. Acute meningitis could be produced by a number of bacteria of pyogenic nature, especially Diplococcus intracellularis meningitidis, the pneumococcus and the streptococcus, the first named, of course, deserving the greatest consideration. In 1897 this diplococcus was established to be the only cause of the disease, being found in thirty-one out of thirty-five cases coming to autopsy. It was found to be present in all acute cases, but rarely in those running a chronic course. The organism was possessed of feeble vitality. The cultures varied in virulence but was found to be constantly present in the epidemics occurring in Massachusetts. It was first described in 1806. Dr. Councilman stated that there had been four epidemics of cerebrospinal meningitis in Massachusetts, as follows: In 1809, 1864, 1874, and 1897. There was a great difference in mortality, ranging from 20 to 75 per cent. In the last epidemic it was 65 per cent. The edidemics were of short duration, but sporadic cases occurred between. Since 1898 there have been 61 autopsies in cases of meningitis occurring in the Boston City and Massachusetts General Hospital; in 13 the diplococcus meningitidis was found in culture, while in 8 cases the disease was considered due to the same etiology, although the organism was not obtained in culture. All cases were primary and did not differ in type from the disease studied in 1897. He said the diplococcus was difficult to cultivate, because of its feeble vitality. There was great need of accurate studies on this subject. Examination of the health statistics of Massachusetts showed a gradual decline 210 cases; in 1900, 165 cases; in 1901, 175 cases; in 1902, In 1897 there were 355 cases; in 1898, 259 cases; in 1899, 240 cases; in 1900, 165 cases; in 1901, 175 cases; in 1902, 165 cases. These cases were scattered over the State and did not occur in sufficient numbers in any one place to be considered epidemic. He believed the cause of the primary cases to be due to the diplococcus intercelluris. It could be concluded from autopsy and statistics that the sporadic cases due to the diplococcus intracellularis were not of frequent occurrence, but there was no way of determining how frequent, because often it was not diagnosed. Up to 1898 he could not find a case in which the culture from the fluid obtained by spinal puncture showed the streptococcus or pneumococcus, which recovered. Every case of meningitis in which the pneumococcus or streptococcus was found by spinal puncture was fatal according to the statistics of the Children's Hospital.

Symptomatology and Diagnosis.—Dr. H. L. Elsner of Syracuse read this paper, limiting himself to an experience of the disease in the central counties of New York State. He said there was not a single year in which cerebrospinal meningitis had not claimed its victims, and that it had occurred both as an epidemic and sporadically. In Syracuse there had been 175 deaths during the past eleven years due to cerebrospinal meningitis; 499 had been reported as being due to meningitis. The deaths during 1899 were 45, that being the greatest number in any epidemic. This disease was very rare after forty years of age. Mental worry and fatigue predisposed to it. The bacteria and culture tests could only give information that was reliable in diagnosis. One attack was supposed to give immunity. He called attention to the occasional occurrences of metastatic joint involvement. In many instances the pneumococcus was found in the joint. In almost all cases Kernig's phenomenon was present. It should be remembered that this sign was occasionally found in other diseases. Kernig himself believed its presence was an early manifestation of the disease, and that it was late in disappearing. In 90 per cent. of the cases of cerebrospinal meningitis seen in six years Kernig's sign was present, and he believed that its early presence, taken in conjunction with certain brain symptoms, permitted an early diagnosis of cerebrospinal meningitis. He did not wish to be understood as saying that Kernig's sign was pathognomonic. When taken as a link it greatly strengthens the chain. He wished to emphasize the fact that the pneumococcus certainly caused cerebrospinal meningitis as it did malignant endocarditis, and without pulmonary involvement. Also

that cases of cerebrospinal meningitis caused by the pneumococcus which occurred in Central New York was uniformly fatal. Also that pneumococcus meningitis might follow distal infections.

The History of Cerebrospinal Meningitis in America.—Dr. Abraham Jacobi of New York contributed this communication. (Read by title.)

Treatment.—Dr. Charles G. Stockton of Buffalo read this paper. When he recollected the difference in virulence in different epidemics it was easy to understand how faulty notions as to the effects of measures of treatment might gain credence. Nevertheless, a timely review of the subject would seem to warrant the conclusion that benefits did follow certain of those measures, and from his own point of view he concluded that the most useful procedure was the bringing about of the best hygienic condition for the patient; that was to say: (1) absolute quiet in well-ventilated, darkened rooms, with the absence of all excitement and irritation; (2) giving the greatest attention to secure the proper performance of the various functions of the body; (3) the trial of the hot baths after the method of Aufrecht in all cases where they seemed to do good; (4) the practice of intraspinal puncture, with drainage where necessary to relieve severe pressure symptoms, to be repeated, if necessary, provided benefit followed the first puncture; (5) the use of antipyrin in cases in which the temperature was raised, not only for the relief of this symptom, but for the mitigation of headache and hyperesthesia. Personal experience had shown him that the drug was also useful in improving the mental state, and it had not been followed, in his hands, by the expected depression; (6) the use of opium or the bromides alone, or in connection with antipyrin, if necessary, for the relief of convulsions, pain, hyperesthesia and pressure symptoms generally, which were not relieved by the foregoing methods of treatment; (7) the use of mercury when needed for its laxative effect, or needed to assist in stimulating the organs of elimination.

The Eye Symptoms.—Dr. A. Edward Davis of New York contributed this paper, first considering all the eye symptoms which might occur in this disease, and then those which occurred prominently in the epidemic of 1904 in New York City. He took up both the motor and visual groups of eye sympoms.

Dr. Morris Manges of New York City opened the discussion. He wished to emphasize the fact that in cerebrospinal meningitis not alone were the spinal meninges involved, but the cerebral meninges and the cortex of the brain as well; bearing these facts in mind he said how hopeless a task it was to attempt much by treatment. The variations in mortality in different epidemics tended to put a damper upon one's enthusiasm regarding the various methods of treatment. If there was a closure of the foramen Magendie local treatment was absolutely hopeless; and yet in all cases we ought to make some attempt to cure the disease by local treatment. A great advance in diagnosis and aid in treatment had been the systematic use of lumbar puncture. In many cases cure had followed its use, and no harm, when done with proper technique, had ever been caused by it. It should be remembered in acquiring this technique one should be prepared for "dry taps." This was not always due to faulty technique. This might be explained by the thickness of membrane or a closure of the foramen Magendie. With regard to the use of antiseptics in the canal, he said it was surprising how tolerant the spinal canal was of foreign substances. In those cases in which we failed to get prompt results from lumbar puncture or injections of antiseptics, such as lysol, we should attempt to drain by making a counter opening above; this with the lumbar puncture below should be of some value in these cases. He referred to the observations made by Dr. Loomis, who made an injection of a silver salt in a severe case of cerebrospinal meningitis. The patient died, and at autopsy the silver salts were found deposited not only in the spinal canal, but also over the cortex and base of the brain.

Dr. Delancey Rochester of Buffalo said that we should bear in mind that in all cases of primary infection of serous membranes there was a certain amount of involvement of the underlying structure, as a rule. He called attention to the fact that recent epidemics occurred at a time when the people kept their houses shut up and away from the fresh air, and that, as a consequence, the vitality of the individual was lowered. In diagnosing cerebrospinal meningitis he said that too much stress should not be laid upon any one symptom or sign, but that they should be grouped together. He referred to the persistence of leucocytosis in this disease from the beginning to the end, and this was a specially valuable diagnostic sign when the polymorphoneutrophiles were in excess. In the treatment of this disease he questioned the value of the injection of antiseptics into the serous sacs, because he believed it could only act as an irritant there, in the same way that it would in the pleural or pericardial sacs. He advocated keeping the patient quiet and as much as possible away from irritation. It was his practice to give the bromides and antipyrins in combination, and to be persistent in its use, at three or four hour intervals and in considerable doses. Such treatment made it possible to move the patient comfortably when giving the baths. The local use of leeches about the base of the skull and along the spine caused much improvement.

Dr. E. Libman of New York said that one of the most important questions regarding cerebrospinal meningitis was the question of the method by which the disease spread. He believed that there was but one organism which caused epidemics of this disease, and that this diplococcus meningitiditis had been found in the nasopharyngeal secretion. He said that two cases had been reported in which meningococcus had been found in the conjunctival secretion. In one case the child had been treated for "pink eye" who later developed cerebrospinal meningitis, and he thought this case proved the possibility of entrance of the organism through the conjunctival sac. Sporadic cases were usually considered to be the milder, but he had in mind exceptions to this rule, one case in particular which died inside of twenty hours, and they recovered the pure cultures of the diplococcus intercelluris.

Dr. E. D. Fisher of New York referred to eighteen cases seen at Bellevue Hispital, in which the meningococcus was found in every case but two; in one the streptococcus and the other the pneumococcus being found. The diagnosis had never been difficult. Lumbar puncture was not necessary to make a diagnosis, but was used in the treatment with benefit. The results in the employment of the lysol injections were not promising. Kernig's sign was not present in such large proportion of cases as related by Dr. Elsner, and he did not place as much value on that sign as some others did.

Dr. E. S. Thomson of New York discussed the eye symptoms.

A Case of Splenic Anemia with Achylia Gastrica.—Dr. I. H. Levy of Syracuse reported two cases occurring in twin sisters.

The New Revision of the United States Pharmacopeia.—Dr. Reynold Webb Wilcox of New York presented this communication.

The evening session was held in the Senate Chamber.

Address.—Dr. Charles. Harrington of Boston, Mass., secretary of the State Board of Health of Massachusetts, delivered an address in which he sketched the origin and the development of the various laboratories in the State of Massachusetts, and told what had been accomplished by them for the public good.

President's Address.—Dr. Hamilton D. Wey of Elmira said that along the skirmish line of medicine militant, in advance of the rank and file of the profession, occurred incidents and happenings surpassing in tragedy and emotion

anything presented in mimic life. He referred to Dr. Ephraim McDowell in the performance of his ovariotomy in 1809; the knowledge of an excited crowd of men were without to do him violence, to the taking of his life in the event of Mrs. Crawford dying upon the table, did not deter him from the performance of his duty, nor rob his hand of its skill and cunning. The application by Ambroise Paré in 1552 of the ligature to vessel ends in amputation, the work of Jenner in connection with vaccination and preventive medicine, the association of the Chamberlains with the obstetrical forceps, the devising of the stethoscope by Laennec, the advancement made by Graves in the treatment of febrile diseases, the efforts of Pinel for the humane and merciful treatment of the insane, were all cited as instances of outposts of militant medicine. Coming down to more recent date, he said we found ourselves under the immediate influence of the achievements of Morton in the production of ether anesthesia, Sir James Y. Simpson's discovery of the anesthetic properties of chloroform and its applicability to the alleviations of pain during child-birth, Holmes' declaration of the contagiousness of puerperal fever, the efforts, researches and investigations of Wiehow and his pupils to render medicine into an exact science through the application of applied methods, the contributions to and labors of Sims and Emmet in the field of gynecology, materialness of Lister upon surgery and surgical technique, and the researches of Pasteur and Koch to elucidate and demonstrate the germ nature of infectious disease. He said that the advances made and benefits accruing to practice of medicine at the present time from laboratory methods and research held forth the reasonable expectation the near future would reveal the true character of the *materies morbi* of most, if not all, diseases, manner of propagation and transmission and indicate scientific and exact procedure of treatment in place of the expectant and empirical plan. In response to the tireless, never ceasing activity of laboratory workers, biologists, bacteriologists and hematologists, new terms and expressions had multiplied, and an almost new nomenclature was given us. It was a great privilege to practice medicine in these latter days. It was not permitted all to be original workers, to be identified with signal advance or achievement in medicine or surgery, but to each it was permitted to maintain the dignity and reputation of the profession by adaptation to the methods of to-day—use of diphtheria cultures for diagnostic purposes, the employment of the Widal reaction in doubtful or suspected cases of typhoid fever, blood examinations in appropriate cases, etc. He said it was incomprehensible that there should be at the present day those who shrank from the employment of or questioned the efficiency of diphtheria antitoxin. Disappointment has been expressed, as in typhoid fever immunization and the serum treatment of this disease, but he said failure in certain lines emphasized success in others, and stimulated expectation as to what the future had in store. Whatever the future contained of promise, there was compensation in present living and relation to the near past, by reason of the Röntgen ray in diagnosis and treatment, the Finsen and other lights in therapeutic relation, intubation, the rôle of insects in the dissemination of disease, the relation of special mosquitos to malaria and yellow fever. For the first time in history war was being waged with regard to preventive medicine, and Japan was demonstrating to the world disablement and death from disease could be made to fall far below that arising from contact and the implements of war, a reversal of past experience. Throughout the State, in villages and small cities, hospitals had multiplied, schools for post-graduate instruction, a feature to the end the practitioner was enabled to familiarize himself with the new medicine, improve his operative technique and quicken his diagnostic skill. These hospitals were also educational factors in their respective localities. He believed there was much to learn from European customs which permitted the savant to continue the study of the various problems of health and disease, under government auspices, secure in his position and without embarrassment of study on account of concern for the matters of every-day life. Dr. Wey said that the sum approximately of $85,000 was available for all purposes in connection with the work of the State Department of Health. The State expended annually 1.17c. per capita for purposes pertaining directly to public health. He thought the time had come for each county to afford laboratory facilities. There should be a county bacteriologist to make blood counts and examinations, diphtheria cultures, Widal tests, and other examinations as related to general every-day practice of medicine.

Second Day, Wednesday, February 1.

The Family Physician.—Dr. Robert P. Bush of Horseheads read this paper and referred to the relation of specialists to the general practitioner, as well as the duties of the family physician to the family and to the community. He also spoke of his influence and his rewards.

Dr. A. Jacobi of New York, said that it was very proper that such a paper should be read now and then, and that the good specialists in the larger cities should be reminded that the family physician was still in existence.

Correction of Nasal Deformities by Subcutaneous Operations. A Further Contribution.—Dr. John O. Roe of Rochester read this paper. He said that in 1887 he presented his first article on this subject before the Society and, since that time, he had presented papers describing various other operations, by which the different deformities of the nose could be corrected by this subcutaneous method without wounding or disfiguring the skin. These subcutaneous operations for the correction of nasal deformities did not demand the bold endeavors of the general surgeon; they, however, required most accurate work and careful attention to details not required in major operations in order to insure the desired result. The success also depended on an accurate knowledge of the plastic art, and to the ability of the operator to reconstruct an organ so as to harmonize both as to its own proportions and in its relations to the neighboring parts. The symmetry of the nose, therefore, was more important than its size. The general shape of the nose should be made to conform to the general shape of the face. In the correction of all facial defects, the surgeon should not only be an artist, but also more or less of a sculptor, with perception of symmetry as related to the different features. In an article read before the British Medical Association in 1888 at Montreal, he classified nasal deformities into two main classes, first, those which affected the bony portion, and, secondly, those which affected the cartilaginous portion of the nose. The special deformities of the different parts he subdivided as follows: first, those affecting the bony portion, which might be too convex or too concave, or deflected latterly, and deformities of the cartilaginous portion which might be due to excessive or defective development of the tip, and those affecting the wings, which might be either collapsed or abnormally expanded. There were other deformities resulting from injuries or from extensive destruction of the hard or soft parts by syphilis, lupus or other diseases, which would not permit of classification, owing to the peculiar distortion of the hard and soft parts. In such cases, however, the method of correcting them by subcutaneous operation was equally applicable and attended with most excellent results. For the purpose of illustrating the manner in which some of these extraordinary deformities might be corrected by the subcutaneous method he cited several cases. In order that these operations might all be performed subcutaneously it was necessary that the incision should be made within the nose. After the parts had been thoroughly cleansed and made sterile, the vestibule of the nose was dilated with nasal spectra and illuminated. A vertical incision was then made through the outer wall of the nose to the under side of the skin. This incision should be made anterior to the deformity which was to be corrected. This incision was enlarged according to the

extent of the deformity, and the skin raised throughout the deformed part. Through this opening the necessary procedure was instituted according to the nature of the deformity. The method that had given him the best results in holding the parts in place until thoroughly united, was a dressing in the form of a saddle made to fit the contour of the nose, held in place by adhesive plaster across the face. It was, of course, necessary to remove it frequently and change its shape in order to conform to the nose.

The Middle Turbinate in Diseases of the Accessory Sinuses.—Dr. J. A. Stucky of Lexington, Ky., said that increase in sinus disease was brought about by the increase in original investigations, and that, perhaps, there was more original work to-day on the accessory sinuses than on any other part of the body from an anatomical standpoint. One of the causes of increase in disease of the sinuses was attributed to the prevalence of grippe. In a résumé of his investigations along this line he said that, both American and English writers had agreed that the middle turbinate was practically an offshoot of the ethmoid and the differences in size and shape was more often overlooked in intranasal diseases than was that of the inferior turbinate. The conditions of the middle turbinate very frequently caused obstruction to the natural openings and interfered with free drainage, such as catarrh and suppurative diseases. The early removal of such conditions decreased the necessity for extensive and more radical operations later. He condemned the use of escharotics and the galvanocautery on the middle turbinate, preferring the use of scissors and snares.

Inferior Turbinated Bone, Its Function, Diseases, and Treatment.—Dr. Wendell C. Phillips of New York read this paper and concluded as follows: (1) Hypertrophy and deformities of the inferior turbinated bone may interfere with respiration. (2) They also interfere with drainage. (3) They give rise to pressure symptoms and subsequently to mental depression. (4) They further prevent proper intranasal hygiene. (5) True hypertrophy must not be confounded with congestion or inflammation. (6) Hypertrophic tissue and portions of the bone should be removed when symptoms and appearances indicate pressure, altered secretions, interference with drainage and the normal functions of the nose. (7) Escharotics should never be employed. (8) The galvanic cautery was of doubtful efficiency. (9) A clean cut by means of specially devised scissors, through both soft tissue and bone, was by far the best method for operation. (10) The snare offered the best method for the removal of posterior hypertrophies. (11) The resultant wound should be protected by a thin layer of gauze moistened with a 12 per cent. solution of acetotartrate of aluminum, to which may be added a few drops of weak adrenalin solution.

Treatment of Chronic Otitis Media, with Illustrative Cases.—Dr. W. Sohier Bryant of New York read this paper and stated that the principal feature was cleanliness, attained by the removal of irritating materials and culture media. Second in importance was the avoidance of irritation consequent on the cleansing process. The objects to be attained were rapid healing of the perforations of the membrane; or if this was impossible, a dermatization of the exposed inner surface of the drum. He emphasized the fact that the only hope for a cure without capital operation was the very careful manipulation combined with the most absolute cleanliness.

Dr. Wendell C. Phillips of New York said that nasal deformities due to syphilitic disease, were the most difficult of all to correct by surgical procedures. With regard to the cure of chronic otitis media with the middle ear and attic necrosed, there was no hope for cure without operation.

The Public Health Laboratory.—Dr. Herbert D. Pease of Albany made a plea for the adherence to the scientific method in the application of the results of fundamental research to the problems of public hygienic work. For this purpose the widest, most searching, and precise methods of observation were necessary. This required all the available technical methods of bacteriological, chemical, and biological examination be utilized. Laboratories for this work could not be economically established by any but the large cities, and, therefore, the State should undertake such work for the other localities. Eleven States had started such work to a greater or less extent. There were at least eleven fields for the application of routine examinations, including bacteriological diagnosis work on diphtheria, typhoid fever, and tuberculosis, water, sewage and milk examinations, and the testing of disinfectants, both chemical and bacteriological; also chemical examinations of food; the preparation of antitoxins and vaccines, and the Pasteur treatment for rabies and the diagnosis of this disease. The methods used in all these lines of work required constant improvement as fundamental problems were developed. Public health laboratories should receive sufficient financial support to enable them to at least do such research work, as their peculiar routine problems showed to be necessary for the immediate improvement of practical sanitation. Some of these problems mentioned were the relation of diphtheria to diphtheria-like bacilli, that of the typhoid to the paratyphoid bacilli, and other problems in the differentiation of bacterial species; also questions of the natural conditions surrounding the viability of pathogenic bacteria. All epidemics of infectious diseases should be studied by laboratory workers, with a view of determining the natural conditions of their development. State technical work in these lines rested on the same claims for support as charitable, penal, and corrective institutions. The educational value of such work was great. There were signs indicating the requirement of a special technical training for prospective health officers. At present sanitary officers' conferences and schools for instruction were to be encouraged and developed.

The Various Methods of Opening the Skull for the Removal of Tumors of the Brain.—Dr. Charles H. Frazier of Philadelphia read this paper. He took up the consideration of the shape, size, and position of flap in tumors of the frontal, temporal and occipital regions, the methods of hemostasis, and the advantages and disadvantages of the various instruments employed in making osteoplastic flaps, together with the closure of the flaps and establishment of proper drainage. Special difficulties associated with exposure of cerebellar tumors was considered. Craniectomies for cerebellar lesions, and exploration for the same was referred to. In inoperable tumors of the brain, patients suffered from headache, vomiting, and disturbance of vision, as the result of intracranial tension; when it could not be localized, or when inaccessible, a section of bone should be removed. He had at present two patients under observation who had suffered very much prior to operation from pain, headache, and vomiting; operation had removed these symptoms, although there was no restoration of vision.

Dr. Curtis of New York said he had done resections of the skull with a wire saw, and found the method a very practical one, although it was by no means as rapid as with a Crile instrument. Three or four openings must be made and delay came in the introduction of the wire saw from one opening to the other. He emphasized the necessity for large flaps, because it made no difference to the patient whether the flap was two inches or larger, and every additional inch in room was of the greatest advantage. He also emphasized the importance of cutting a skin flap larger than the bone flap, so that when the whole flap was raised up the edges of the skin could be turned over and fastened by sutures, turning in their edges.

Railway Spine.—Dr. Edward B. Angell of Rochester presented this paper and said that the earlier pathological explanation of railway spine was largely speculative, that spinal cord injuries presupposed unusual violence, and that the disturbance, in truth, was a psycho-neurosis, in which imperative ideas played an important part. Discrimination between objective signs significant of an organic

disease and subjective symptoms characteristic of functional disorder was made and illustrative types described.

Drs. KINNEAR and FLOOD of Elmira, discussed this paper.

The Relation of Pelvic Conditions to Nervous Disorders.—Dr. A. L. BRAHAN of Canandaigua referred to the frequency of sclerosis of the appendix in females and the relation of this chronic form of inflammation to menstrual disturbances. He said that sclerosis of ovarian tissue, the thickening of the ovarian capsule, aborted ovulation, with hematoma or small cysts, and later, rupture of these into the abdominal cavity, with adhesions about the ovaries and tubes, often fused these together. The result of this pathological condition upon the physical life of the woman, especially the nervous system, should be carefully measured, and the means for restoration to health needed to be broadly estimated.

Drs. EDWARD B. ANGELL of Rochester, EDWARD E. FISHER of New York, B. C. LOVELAND of Syracuse, and CLAUSEN of Victor, discussed this paper.

A Resolution from the Committee on Legislation.—Dr. FRANK VAN FLEET of New York, in behalf of this Committee, presented the following resolution, which was unanimously carried:

"Whereas, information from reliable sources has been received that certain opticians, forming the New York Optical Society, contemplate the introduction of a bill in the Legislature, "Defining and Regulating the Practice of Optometry," which is designed to confer on these opticians the right to employ [illegible] for the relief of symptoms which may or may not be due to defective eyes, and

"Whereas, information from other and equally reliable sources is received that certain people, confident in their patronage of medicals to which [illegible] the [illegible] of massage, therapeutic gymnastics, Swedish movements, [illegible], vibration, vibrassage, and other terms, desire at the hands of the Legislature the legal [illegible] and [illegible] in the practice of medicine; and

"Whereas, we believe that the present needs connected with the necessity and proper protection of the people, should be given [illegible] who practice the healing art, and that the medical laws of the State of New York are adequate enough to permit the practice of any and all practices which have as end to be desired by the patronage or relief of diseases;

"Therefore, be it resolved that the Medical Society of the State of New York deprecate these efforts of misguided people to secure the passage of [illegible] and be it further

"Resolved, that the Medical Society of the State of New York petition the Legislature to refuse to enact any law which will in any way discriminate either for or against any class of people who claim to have any peculiar methods which may or may not be valuable for the treatment of disease, or of cripples and deformities of the human body.

"Resolved, that a typewritten copy of this resolution, signed by the President and Secretary of this Society, be placed in the hands of every member of the Legislature, including the Governor and the Lieutenant-Governor."

The Non-Sequitur in Medicine.—Dr. HENRY A. FAIRBANKS of Brooklyn said that in the past largely, and to some extent at present, metaphysical speculation had invaded the domain of medicine. A variety of assumptions, with inferences based thereon, had led to results having no agreement; on the other hand, speculating had dealt with facts in such a way as to lead to fallacy. Exact knowledge of facts, laws and approximate causes, the characteristic of medical study to-day, he said, must evolve unity and firm basis of procedure. The looking upon disease as a simple and not a complex matter, with all of its consequences, was the non-sequitur of medicine to-day. Unwarranted assumption led to that in the early days of medicine. Unqualified claims for therapeutic measures had propagated it. Unscientific statements still kept it alive. Our clinical teachers and pathologists and their carefully kept records rang out the answer to it; diseases, instead of being simple, were the most intricate subjects presented to the student for consideration. So interdependent were the various structures of the body for their nutrition, function, growth, and welfare, and so intimately bound together by the sympathetic system, that when disorder was manifested by one, it became necessary to define its relation to the rest of the economy. Satisfactory diagnosis and treatment could not rest upon the examination of one organ alone. The indiscriminate distribution and use of drugs, the origin of various medical vagaries, could be traced to the fallacy named. We must look to the medical doctor for its correction. He could not inculcate the fact too often that it required a very thoroughly trained and careful mind not only to unravel this complex subject, disease, but to select and apply the appropriate remedies for its relief.

Poisoning by Potassium Bichromate.—Dr. FRANCIS EUSTACE FRONCZAK of Buffalo reported such a case and drew attention to medical jurisprudence literature, which was very meager on the subject, there being less than six cases mentioned of such poisoning. The case reported by the speaker was one in which an attempt was made to kill a woman by mixing about 100 grains of potassium bichromate with [illegible] and boiled. The doses usually given in books were one-twelfth to one-half a grain.

A Study of Two Hundred Osteotomies for Genu Valgum and Genu Varum.—Dr. HOMER GIBNEY of New York made a report of these cases, which had occurred during his service at the Hospital for Ruptured and Cripples. By great majority of cases admitted were genu varum, or bowlegs, the proportion being about two-thirds as many bowlegs as genu valgum, and these deformities were more frequently met with in males than females. He then described his method of procedure briefly.

The Etiology of Hypertrophied Prostate.—Dr. L. BOLTON BANGS of New York read this paper. (Will be published later.)

Some Observations on the Technique of Perineal Prostatectomy.—Dr. GEO. R. FOWLER of Brooklyn said that the [illegible] route was the one of choice, but that it must be [illegible] there were cases in which the perineal route had [illegible]. In fact, there were no hard and fast rules which could be laid down. It was his belief that in the great majority of cases of hypertrophy of the prostate were best reached by the natural route of the perineum, but under enucleation necessarily demanded a total [illegible]. Again, drainage was best instituted by this route. The capsule could be entered almost anywhere, and it was possible to perform a relatively complete prostatectomy without entering the urethra. When traction was properly applied it was not necessary to make pressure from the rectum, as was frequently the case when the suprapubic method was employed. The fears of infection of the deeper pelvic planes were ever present by the suprapubic method. Dr. Fowler then described the steps of the operation. No reference was made to traction upon the organ as an aid to enucleation or resection, because he did not believe it was at all necessary; he grasped the corresponding lobe with a double tenaculum forceps, which gave him absolute control of the situation. In the after treatment he emphasized the importance of getting the patient out of bed as soon as possible. If drainage was employed, the tube should be removed not later than forty-eight hours after operation.

Personal Experiences in Prostatic Surgery During the Last Two Years.—Dr. WILLY MEYER of New York said that to-day it was a question of choosing the proper method in any given case. The surgeons usually recognize the necessity of individualizing in these cases, and could choose one of the three methods, giving it a fair and unbiased

test. Each method had its merits. A well-to-do patient might be allowed to practice self-catheterization if he was opposed to surgical intervention, but for the rank and file so soon as a man came to catheter life surgical interference should be advised. In trained hands the death rate following operations was less than five per cent., and often but two per cent. He did not believe any surgeon had a right, under these circumstances, to relegate the patient to catheter life unless he absolutely refused the knife; in which case the Bottini operation should be advised. The superpubic operation seemed more promising as regards sexual power. In conclusion he said that we had to-day three useful methods, viz.: the superpubic, the perineal, and the Bottini; that these three methods deserved to be recognized as standard procedures; where the conditions warranted it prostatectomy should be done; the selection of the route, whether superpubic or perineal, was not an easy matter to choose at present; the question of the preservation of sexual power was important; if the operation by knife was refused the Bottini operation should be advised; the catheter should never be intrusted to a patient for regular use; the surgeon should familiarize himself with the perineal, the superpubic prostatectomy as well as Bottini operation in order to do justice; always select the operation that suited the case.

Prostatism without Prostatic Enlargement, its Diagnosis and Treatment.—Dr. Charles H. Chetwood of New York said that there was no doubt that prostatism could exist without prostatic enlargement. The important symptoms were urgency and frequency in urination, pain after the act, and a partial or complete retention of urine. This collection of symptoms in an individual past the age of forty was more likely to suggest to the medical observer an obstructing prostatic hypertrophy rather than the malady about to be described. Some years ago he first described this condition under the title of "Contracture of the Neck of Bladder." This condition was a fibrous stenosis of the vesical orifice. The cause might be found in any previous chronic inflammation in front or behind the sphincter vesicæ and more frequently of gonorrheal origin. The condition was found in the young as well as the aged. He said that confusion existed in the minds of many men regarding prostatic hypertrophy and contracture of the neck of the bladder. Dr. Chetwood here related a few cases, one of which gave a history of prostatism when there was no prostate present. A normal vesical orifice should freely perience justified the conclusion that contracture of the neck be present the finger would not be admitted. Many cases of prostatic hypertrophy were operated upon without the recognition of contracture of the vesical orifice and resulted in failure. He then referred to the effective means for the relief of the condition. A simple incision into this stenosed ring was likely to be attended with severe hemorrhage, but the galvanocautery operation was safe and effective. He presented an instrument specially devised by him for use through the perineal incision. His experience justified the conclusion that contracture of the neck of the bladder was one of the causes of vesical obstruction and that relief could be had, safe and sure, by means of the galvano-cautery instrument introduced through a perineal incision.

Superpubic Prostatectomy.—Dr. Howard Lilienthal of New York said that his experience with thirty-one cases enabled him to state positively that the superpubic route was the safest and the most thorough of all operations for the relief of prostatic obstruction. Twenty of these cases were his own and eleven were operated upon by his colleague Dr. Joseph Weiner. Another case seen years ago, but not in the hospital, had resulted fatally. Recovery occurred in every one of the thirty-one cases in the hospital, and there was a perfect functional recovery in all but two. The sexual power was increased after operation in a number of instances, and was lost in none who were potent before operation. Most of the patients were feeble and had various complications. Dr. Lilienthal here briefly narrated the various steps of the procedure, and believed that success could be in the hands of others as it had been in his own. The operation itself was so simple that any surgeon with ordinary skill could hardly fail to attain success.

Has the Catheter a Place in the Treatment of Chronic Prostatic Hypertrophy?—Dr. Paul Thorndike of Boston read this paper by title.

Conservative Perineal Prostatectomy; Results of Two Years' Experience.—Dr. Hugh H. Young of Baltimore agreed that there was no one method for the treatment of prostatic hypertrophy. Seven years ago he first performed this operation by the superpubic route, which was followed by such wonderful results that he thought that the ideal had been attained. But after having had three deaths in twenty cases, and having had cases in which there was a tedious convalescence, he then thought that there were other methods which might produce better results, especially in aged patients. He then turned his attention to the Bottini operation, and he was surprised then to find such wonderful results from an operation which he once considered utterly unsurgical. Then came unexplainable failures. Among eighty-five cases operated on by the Bottini method there came some deaths which should not have occurred. There were six deaths among the eighty-two cases. He then turned his attention to the perineal route. Although an admirer of Dr. Parker Sym's instrument, he thought something better might be accomplished by a metallic instrument which he devised. This instrument was here exhibited and described. During the past two years he had had seventy-five cases. After briefly referring to the technique, illustrating it by diagrams, he said that in all these seventy-five patients normal urination had resulted in all but two in one there was a residual urine of 300 c.c. and in the other 150 c.c. There were no operative deaths in any of the seventy-five cases. In a large proportion of the cases sexual power and erections had been preserved. Epididymitis was extremely rare, because he preserved the urethra and the ejaculatory ducts. The advantages of the operation he devised were: (1) the prostate was attacked at the nearest point, and also the whole obstruction of the prostate was in better view and under the control of the eye, (2) he was able to preserve the urethra and ejaculatory ducts and avoided injuring other structures better than when he used some other form of transperineal operation, (3) the introduction of a small instrument did not add to the gravity of the operation, and there could be no objection to such traction he used which touched the gland, (4) the incision was utilized for valuable drainage, and did not prolong convalescence; (5) the preservation of the sexual power in a fair majority of the cases was worthy of recognition.

Cases of Incontinence as a Result of Prostatectomy.—Dr. F. Wood Rugles of Rochester contributed this paper which was largely a review of the literature upon the subject.

Lantern Slide Exhibition.—Dr. Francis S. Watson of Boston presented some lantern slide views of prostates. He paid a glowing tribute to Dr. Gouley of New York as being the originator of prostatectomy in this country, and the operation practised by Dr. Gouley was the one used by Dr. Watson and Dr. Goodfellow in preference to any other.

Dr. Albert Vander Veer of Albany emphasized the importance of diagnosis. Fifteen years ago he and Dr. MacDonald performed this operation with an instrument similar to a drawing knife, removing the middle lobe. He believed that some respect was due the catheter, and such cases as were described by Harrison were relieved by the large sound and catheter. He noted that in all the papers read there was a conservative tendency to retain or restore the function of the remaining organs or parts of organs.

Dr. Samuel Alexander of New York said that in 1894 he had the honor of first making a contribution in refer-

ences to operations upon the prostate for prostatic enlargement. At that time prostatectomy was on the decline and castration and operations upon the vas were in the ascendant. It seemer strange to him that there was such a revulsion of feeling as was shown in the words of those who had spoken. He believed that it was only right that all honor should be given to McGill of Leeds, England, for placing prostatectomy for the first time upon a proper surgical basis. The superpubic operation of McGill was practically the one used to-day. He emphasized the importance of a thorough knowledge of the anatomy of the prostate.

Dr. Willis G. MacDonald of Albany said that for nearly twenty years he had been operating upon the prostate, and had employed every form of operation which had been advised. He could not understand how one could successfully, accurately, and skillfully remove the prostate unless he could see what he was doing. The anatomical operation was based upon the anatomy of the perineum, and the attack upon the prostate should be made not by touch of the finger so much as under direction of the eye.

Dr. Parker Syms of New York continued the discussion. He said that the work of Dr. Alexander, the perineal prostatectomy aided by a superpubic incision, was most successful and scientific. It seemed to him that a suprapubic opening made in the bladder for the purpose of reaching the prostate was entirely unnecessary and unscientific. Dr. Syms had devised a tractor which consisted of a rubber bag on the end of a rubber stem, which he introduced into the bladder through the membranous urethra; it was then dilated, and this made pressure upon the prostate and held it in place, and made it very easy to enucleate that gland after the sheath had been split. When this instrument was first devised by him he thought that such aid was necessary, but he had since learned that it was not. He said the prostate could be enucleated through a median incision in the perineum in from five to six minutes, and with but little damage to the patient, and subjecting him to but little shock.

(To be continued.)

New Instruments.

AN ABDOMINAL SPOON.

By CARL BECK, M.D.,
NEW YORK.

The shape of the instrument, here illustrated, explains its purpose. Whoever has been embarrassed by the repeated protrusion of intestinal loops, while uniting the margins of a peritoneal wound, as so often happens when the anesthesia is imperfect, will appreciate the value of this "abdominal spoon." It prevents the intestines from being injured during the sewing procedure, because the point of the needle is directed against the instrument, which pushes the intestines back at the same time. So the whole peritoneal wound is in fact sutured over the instrument, which is gently pressed down at its handle by an assistant. The spoon can also be used as a blunt re-

tractor in intraabdominal operations, especially on the liver and gall-bladder.

When I first conceived the idea of this protector, I thought that some similar instrument must exist; therefore I looked over the catalogues of instrument-makers, but in vain. I asked the firm of Windler, when I was in Berlin two years ago, to make one for me. I have used the instrument ever since with great satisfaction. It consists of cheap metal and its length is eight inches.

THE ATTRACTIVE FEATURES OF GRADUATED TENOTOMIES UPON THE EYE-MUSCLES.

BY AMBROSE L. RANNEY, A.M., M.D.,

NEW YORK

Is it possible that a surgical procedure of any kind can possess attractive features to a sufferer who meditates it? It certainly seems at the first glance a paradox to answer "yes" to this inquiry.

There are in every large city thousands of sufferers who have borne each day for years more inconvenience and greater physical suffering than some surgical steps involve; yet who are too easily dissuaded from taking the radical and curative step for a physical ailment, not only because of ungrounded fears on their part, but because of a severe condemnation of such a step by ignorant relatives and friends, and also by some medical advisers. Such sufferers are constantly seeking in vain through every possible channel (but the right one), to escape even the suggestion of that alarming word to all laymen—a "surgical operation"—as a means of cure.

The clinical histories of twenty selected cases which I publish here demonstrate, I think, beyond cavil or dispute that rapid and permanent cures of many forms of nervous derangements which had no apparent connection with eye-strain and which had proven to be incurable by drugs have been effected through the surgical relief of eye-strain, which in consequence has become attractive to the sufferer.

I recall an instance in my past experience that illustrates well the wide-reaching effects that often follow even a suggestion of surgical relief for physical ills:

CASE I.—Many years ago, a prominent physician of the East sent his only son to me for the express purpose of ascertaining if "eye-strain" could be the cause of repeated physical break-downs, and an inability to use his eyes for any length of time, without great distress, while endeavoring to complete his college course. He had been previously examined from time to time, by several physicians, and his eyes, also, had been repeatedly tested by oculists of repute; yet nothing had ever been found to account for the symptoms, nor had any suggestions been offered that afforded permanent benefits.

Fortunately, the father of this young man had become thoroughly imbued, through familiarity with my office work, with the scientific character of certain steps, whose recognition I was then fighting for against the bitterest of professional opposition; and he felt personally satisfied that if his son was ever to be restored to health and usefulness in a profession, it was to come through scientific and modern tests for eye-strain, and radical correction of the cause.

I found, after several careful tests* of his son's eyes, that he was on the border-line of a convergent squint; that "he saw double-images" at times; that he had diplopia with the red-glass test; and that eye-strain was the probable cause of a nervous leak that had already unfitted him for his work.

I told the young man that I proposed to correct his "tendency to a cross-eye" by two painless graduated tenotomies (made upon the internal rectus muscle of each eye); that these surgical steps would not confine him to the bed, or even to the house, but for one day in case the weather was inclement; and I assured him, also, that I believed that after the two surgical steps which I advised, he would soon be able to finish his college course, and to study a profession without any of his former "break-downs."

Now follows the interesting and instructive part of this narrative. It seems that this young man was engaged to be married to a daughter of one of the prominent men of this city. The very suggestion by me of an "operation" upon the prospective son-in-law, created dire consternation at once in that family. He was immediately taken to another oculist in New York City (for confirmation of my view) without my knowledge or consent. The oculist in question did not know—nor did he (in his prejudiced attitude) apparently want to know, much about eye-muscles or their anomalies. He had none of the modern instruments—which are to be found to-day (thanks to a bitter fight), in the offices of most oculists. He, therefore, did just what the other oculists (of his class) had done before to this young man—viz., he tested his refraction (which was normal); smiled derisively; assured the patient "that he was all right"; and congratulated both him and the prospective bride's family that one victim had escaped so fortunately from mutilation at my hands.

After they had departed he sat down and penned, without solicitation—purely from the goodness of his heart—a letter to the father of the young man—a letter that would have carried terror to the heart of most parents; a letter that surely was intended by him to carry a poisoned arrow for my own breast; a letter that ought to be framed to-day as an instructive one for those young doctors who believe that great reputation and great success must always go hand-in-hand with honesty and fair-dealing. This letter was immediately forwarded to me by the father (on receiving it), with his written instructions to treat his only child as I deemed best—one of the most remarkable evidences of faith and confidence on record in my office. This letter reads about as follows:

Dear Dr. ————,

I find in your son no evidence that glasses are required; nor do I find any conditions that justify an operative procedure.

I feel it, moreover, to be my imperative duty to you, and to myself, to warn you against the *butcher of Madison Avenue;* and to state that irreparable injury must certainly result to your son if operations are performed upon his eye-muscles.

Respt. yours,

———— M.D.

* The details of modern eye-testing are given in full in the author's work, entitled "Eye-Strain in Health and Disease." Philadelphia, F. A. Davis Co., Publishers.

Within two weeks from the receipt of these instructions I carried out my original plan of procedure. I performed two graduated tenotomies; one upon each internal rectus. I *cured the young man of all his symptoms, almost as if by magic.*

He subsequently finished his college course without an eye-symptom, and with steadily improving physical health. He immediately thereafter studied a profession. He is to-day a successful and prominent member of that profession; and has never had a relapse of his eye-symptoms or a physical breakdown. Yet that kind-hearted and generously disposed oculist (who predicted in his letter to an anxious parent untold woes and disaster to any "victim" of the butcher of Madison Avenue) might through his ignorance have prevented this permanent cure and subsequently had to congratulate himself on keeping one sufferer, at least, from all hope of recovery.

This "victim" sees to-day in tenotomies some very attractive features! A good education, and all that he holds dear in life, have been made possible to him through a surgical step.

Case II.—In the early days of my work upon derangement and anomalies of equilibrium of the eye-muscles, a wealthy lady from one of the Western cities was under my care. One morning she brought with her into my office a niece who was suffering greatly from what had for years been diagnosed by many oculists as a "stoppage of the tear-duct" of one eye. She had had this tear-duct dilated for many years prior to this visit (by the passage of a probe through the duct), at regular intervals by oculists, both at home and abroad. This *step was intensely painful to her*; and no cure of her sad condition seemed possible to her from her past experiences.

The tears flowed more or less constantly over one cheek, causing the skin of that cheek to be badly excoriated and the face to be somewhat disfigured in consequence. For years she had carried a handkerchief almost constantly in her hand to mop this cheek with, and to prevent the overflow of tears as much as possible.

I found, by a careful examination, that one eye was several degrees higher in the orbit than its fellow;* and I at once put a prism temporarily over her distance glasses to afford relief mechanically by bending the ray of light. Almost immediately the tears ceased to flow over the cheek. She wore the prism for twenty-four hours, at my suggestion, and reported to me that " a miracle seemed to have been performed;" because all annoyance from an overflow of tears had been completely arrested for the first time in many years.

As the wearing of a heavy prism in combination with her glasses had great disadvantages, I proposed to her, that a graduated tenotomy be at once performed, as a means of lowering the high eye. This was done in five minutes, without pain, and in my office. She made social calls the same afternoon.

The effect of this trivial operation was an immediate and permanent cure. This patient has not for many years had her tear duct probed (as she formerly did prior to the operation); she has no longer any disfigured cheek; she no longer has to constantly carry a handkerchief in her hand; and she has greatly improved in her general health.

To-day, patient No. 2 sees (as did No. 1), some attractive features in tenotomies. The pain of each probing of her tear duct was severe—the operation was painless.

Case III.—A charming young lady came into my office yesterday, after an interval of over two years since her last visit. She carried her head erect, was a picture of health, and in the best of spirits. Yet this same person came into my office several years ago, with her head drawn rigidly toward her shoulder, her face distorted with unceasing pain that had persisted for two years, her neck muscles like bars of iron, her body emaciated, and a small pillow packed tightly between the bent head and the shoulder, in order to support the head. She had used this pillow constantly both day and night, in doors and on the streets, for nearly two years; had obtained sleep and a diminution of her pain only by large doses of opiates; and had come at last to New York to consult Dr. Robt. T. Morris regarding a division of her neck-muscles. Dr. Morris gave an unfavorable opinion of this surgical procedure and kindly referred her to me.

Several graduated tenotomies were required to put her eye-muscles into proper equilibrium. I performed them all within a space of three months. The result was a complete cure of her pain and deformity.

Since then she has been a teacher; has used her eyes constantly; has steadily improved in health; and has had no return of her deformity—although her neck muscles once became stiff when her glasses were broken, and she had to go without them for several days. A return to wearing glasses caused the temporary rigidity of her neck muscles to disappear at once.

Patient No. 3 has (like the preceding) good cause to-day, to see some attractive features in tenotomies of the eye muscles. "Whereas, I was sick—now I am well"!

Case IV.—Some twelve years ago a married woman from the West was referred to me by Prof. A. Alexander Smith, M.D., of New York. She was having "grand-mal" attacks of epilepsy, at very frequent intervals (several occurred in one week); and, when I first saw her, she was taking her meals in a private parlor of the hotel, to avoid the possible mortification of a fit in the public dining-room, while away from home. She showed no refractive error—even when atropine was employed.

One graduated tenotomy upon an eye-muscle immediately stopped her fits. For the past twelve years, she has been practically a well woman—although one or two "faint" attacks have been reported to me, without convulsive movements. She must, by this time, have nearly reached the "menopause."

This patient also sees, to-day, some attractive features in graduated tenotomies upon the eye-muscles. I have seen this patient many times since the operation, when visiting New York, and she seemed the picture of health and high spirits. She has taken no drugs, to my knowledge, to control epileptic seizures since I performed the tenotomy.

Case V.—An epileptic was referred to me by my friend Prof. Geo. M. Edebohls, M.D., of New York City, about four years ago. This well-known surgeon had personally seen much of my office methods and results, while he was personally under my care for several months for uncontrollable headaches, of years' standing, that were cured by me through graduated tenotomies upon his eye-muscles. He, therefore, advised this patient to seek my advice and possible aid.

Careful tests made upon the eyes of this epileptic patient disclosed a marked tendency toward a convergent squint. Graduated tenotomies were per-

* The reader is respectfully referred to the author's work, entitled "Eye-Strain in Health and Disease," F. A. Davis Co., Philadelphia, for full information regarding this ocular anomaly.

formed by me upon both of the internal recti. His refraction was practically normal; hence no glasses were prescribed. No epileptic seizure has occurred since the first tenotomy.

This patient (like those previously mentioned) has to-day reason to see some attractive features in tenotomies.

Case VI.—About twenty years ago, I saw an insane patient brought into the office of an oculist of this city, from one of the asylums of this State. There could be no question as to his insanity—which began when the patient was in a religious revival about two years prior to this visit to New York.

Two photographs of this patient were subsequently published*—and I take the liberty of quoting from the published history of this case the following paragraphs:

"When first seen he was stolid, refusing to speak, and sadly demented. He wept aloud and wrung his hands much of the time. He refused food, and, indeed, for many months had only taken it as it had been placed in his mouth by others. If standing, he held his arms out in an imbecile manner, with the fingers spread apart. The saliva drooled in streams from his mouth to the floor. He was thin and pale, and a cold moisture covered the skin. In this pitiable condition it was difficult to obtain exact information of the ocular conditions; but, by the exercise of much patience, these conditions were sufficiently made out to enable a generally correct judgment to be formed."

I personally saw this patient transformed into a perfectly sane and healthy being by three graduated tenotomies within a few weeks. When he returned home, he ate abundantly of his own accord, and was in every way perfectly sane and normally buoyant. As far as I have learned, there has been no return of insanity.

This patient has had reason to see some attractive features in tenotomies.

Case VII.—Nearly twenty years ago, one of my friends (a prominent attorney of this city), brought his wife to my office in a carriage to see if something could not be done to improve her physical condition. For over sixteen years this invalid had seldom left her room. She was not, as a rule, strong enough to even spend an entire evening in the company of her immediate family. She read almost constantly. She stated to me that "she had always regarded her eyes as the only strong organs that she had." After much careful observation and testing of her eyes, normal refraction was found; but it was deemed wise to let out the internal muscles. Two graduated tenotomies were performed by me within a month from the date of the first visit.

Three months later the husband exclaimed, on meeting me casually on the street, that the results obtained by my treatment of his wife was "not one of cure, but one of resurrection." He stated that she was tiring him out attending social engagements and places of amusements that she had not visited for nearly twenty years. No relapse of her old symptoms have ever occurred. She continues to have perfect health to this day.

This patient, too, sees to-day some attractive features in tenotomies.

No patient whose case is in my record books has greater cause for gratitude and rejoicing.

Case VIII.—A carriage drove up to my door one morning, about eighteen years ago, and a young woman was taken from it, and carried by two men into my reception room. She had been brought from one of the New England States, to see if she could possibly be restored to health from a complete nervous collapse that had suddenly developed while she was away from home in a fashionable school for young ladies. Two years had elapsed since this attack; yet, under the best of medical advice, massage, electricity, and drugs, all had yielded negative results. She could walk but a few steps, and had been carried daily to and from her bedroom.

Within a few days from the first visit to my office, I felt justified in performing graduated tenotomies upon both internal recti muscles, for a marked tendency toward a convergent squint.

This patient regained her ability to walk, as well as any woman of her age, within three months. Subsequently, she studied physical training. When I last heard from her she was employed as a teacher of physical culture in some educational institution.

The patient is another of those who see, to-day, some attractive features in tenotomies.

The restoration to health after the relief of eye-strain was almost miraculous to her family, her medical advisers and her friends.

Case IX.—In the year 1891, when on the eve of departure on my yacht, I was visited on board by a sailing master of a yacht that lay at anchor nearby. He was in tears and evident mental distress. He stated, between his sobs, that his little daughter had suddenly developed paralysis after an attack of St. Vitus' dance, and that a diagnosis of brain-tumor had been made that day by a leading neurologist of New York City, after a very careful and prolonged examination. The prognosis given by that expert had been exceedingly grave.

He requested that I postpone my departure for one day and examine his child at my office on the following morning. This I consented to do, because of the extreme exigencies of the case.

The child was then about 8 years old. She was unable to walk on account of a paralysis of the right leg; and the arm and face seemed to be seriously affected as well. She talked with difficulty, drooled some at the mouth, and used the arm but slightly. This paralysis had developed suddenly. It had been preceded, however, by spasmodic movements of the arms and legs of the St. Vitus' type, for some months.* Under atropine, this child showed only a slight degree of hypermetropia; but she disclosed a very high degree of muscular error, that bordered closely upon convergent squint. Prismatic glasses were prescribed by me for constant wear, until I returned from my summer's cruise. Subsequently I performed graduated tenotomies upon both internal recti.

The result of this treatment was a complete restoration to health. This patient graduated with honors lately at a college, and has become a fine pianist.

I have, to-day, a photograph of this patient taken on the eve of her graduation. She has developed into an unusually handsome and vigorous woman; weighs about 150 lbs., and has never shown any choreic or paralytic symptoms since the tenotomies were performed, and her eye-strain thus arrested.

Surely this patient and her family see, to-day, some attractive features in tenotomies.

Such a remarkable recovery from so grave an outlook, justifies a hopeful prognosis in all cases where eye-strain exists.

Case X.—One of the most remarkable cases on my record-book was brought to my office by my old

* "Functional Nervous Diseases" (page 123), by Geo. T. Stevens, M.D. 1887. D. Appleton & Co.

* A full report of this case and also of other similar cases has been published by me in the book above mentioned on "Eye-Strain in Health and Disease."

and cherished friend, Prof. Ralph Waldo, M.D., of New York City, about 1889.

This case has special interest because some symptoms that pointed strongly toward the existence of organic disease of the spinal cord had been steadily progressive for months. The patient had also been a victim to marked diabetes for some years, and had been under medical care for that condition for a long time. His physician was more than astonished when he noted an immediate and complete disappearance of sugar in the urine within a few days following the first graduated tenotomy which I performed upon this patient. He watched for months for its return. This never happened, as far as my records show. The patient made so complete a recovery while under my care after a correction of his refraction by glasses and two tenotomies (that brought his eyes to the same level) that he performed the labor of at least two ordinary men for many years in his enormous business, and died some twelve years later of some acute pulmonary disease.

He had been a terrific worker in his business for many years. One of his most arduous duties was to sign all the checks for one of the largest firms in America, of which he was a member.

He began to notice, about two years prior to his visit to my office, that his right arm was becoming weak, and that writing with it was getting more difficult and uncertain each week. He therefore began the training of his left hand to write, and when I first saw him he was using the left hand almost entirely for signing checks and personal correspondence. He thought that there was an apparent progressive muscular atrophy about the right thumb, and its development as a sequel to his diabetes caused him great alarm. Several physicians had made a diagnosis of organic disease of the spinal cord, and had advised him to give up at once all business cares and the confinement connected with office work.

He came to my office chiefly for a diagnosis and for treatment by static electricity, if I deemed it advisable. His right hand certainly seemed to me, at a glance, to be very much atrophied about the region of the thumb; but, as both hands were extremely bony and thin, and as he was very nervous and also excessively disturbed over his condition, I decided to first test his eyes before I discussed with him the possibility of some organic spinal disease.

It may be well in this connection for me to explain to my readers how eye-strain can be related to diabetes. This is not the only case in which I have observed an arrest of diabetes by operations upon the eye muscles which were done by me for the relief of other nervous disturbances. Such recoveries were very startling to me when I first observed them, and their physiological explanation is probably as follows:

1. We know that the "diabetic center" in the medulla produces diabetes *only when irritated*—not when destroyed.

2. We know that the centers which control the movement of the eyes are also situated in the medulla in close anatomical relationship with the diabetic center.

3. We have reason to believe that eye-strain in any aggravated form (when due to anomalies of adjustment of the ocular muscles) may, in time, create a hyperemia of the medullary centers that are called into excessive action to adjust for such anomalies.

4. It is not irrational, therefore, to suppose that contiguous medullary centers may likewise become involved to a greater or less degree in consequence, and be also stimulated (as a result), to abnormal action.

For example, any occupant of an apartment (with thin walls) might become, in time, greatly disturbed and upset by constant drumming upon a piano in an adjacent apartment, especially if the pianist was a beginner who played discords constantly and who practised day and night to acquire the proficiency, which he sadly lacked. So it may be with the diabetic center in the medulla, when the centers that control the movements of the eyeballs are overtaxed from some congenital defect in the eye muscles and are constantly kept in a state of abnormal tension.

I expect, at no distant date, to publish the clinical records of all cases that I have personally observed where the relief of eye-strain by graduated tenotomies has been followed by a very marked amelioration or total cure of saccharine diabetes of long standing.

Such cases (when published with full details) may possibly shed some light upon a condition that is quite common in adults over fifty years of age, but, fortunately, not so unfavorable in prognosis as when developed earlier in life.

Patient No. X. had good reasons (for years before his death) to see some very attractive features in tenotomies.

He was a very active worker for twelve years in disseminating among his friends the view that eye-strain is often the cause of most obscure nervous derangements.

Cases XI., XII., and XIII.—Among the medical converts to my views in the nineties, that has kindly referred several obscure and puzzling cases to me for investigation and treatment, was my friend Dr. E. W. Hedges of Plainfield, N. J. Three cases of genuine epilepsy (that were unmistakable in their type) were sent to me from this source. All made complete recoveries without the aid of drugs—one by the use of glasses alone, and two by graduated tenotomies.

These cases have been published (with all details of treatment, personal letters from physicians and the patients themselves, and other data) in my work entitled "Eye-Strain in Health and Disease," and in the *New York Medical Journal* of December 3, 1904.

The first of these was a case of "grand-mal" seizures of the most violent type. She has now been absolutely free from fits since the last tenotomy—a period of about twelve years. Reports have been received by me from time to time, from this patient, that express the greatest gratitude; and uninterrupted health seem to have been permanently established by the tenotomies.

The other case was one of "petit-mal" seizures—a type of epilepsy that is generally regarded by neurologists as extremely grave in prognosis. He had (as shown by my records) one hundred and six attacks in fourteen days, prior to tenotomy—after stopping the internal administration of bromides. He had practically no refractive error; hence no glasses were ordered for this patient.

The last report that was received from this case stated that "no seizures have occurred for over four years."

Both of these patients must see, to-day, some attractive features in tenotomies.

To be relieved from the dangers and mortification of epileptic convulsions without drugs is certainly a remarkable result.

Case XIV. is one of the most remarkable cases of complete restoration to health (after tenotomies), from an apparently hopeless loss of mental faculties, that I have ever seen. I saw this patient first on May 30, 1889.

The records of this startling case were originally published by me in my work on eye-strain. It is one of the most wonderful recoveries, I think, on

record. It certainly teaches that we, as physicians, can all be mistaken in making a positive diagnosis of organic disease. This patient is seen by me almost every year, whenever he visits New York. His recovery was complete and is permanent. He now weighs over forty pounds more than when I first saw him, thirteen years ago; and he is to-day in perfect health physically and mentally.

This pitiful sufferer was led into my office (as a child would be led) one morning by his wife. From her I obtained the following history: It apparently justified fully the suspicion of advanced softening of the brain held by physicians who had been consulted.

The wife gave to me these details that bore upon the diagnosis and hopeless prognosis: There had been steady emaciation and mental failure for many months. Gradually the patient had become like a child in mind; had to be cared for like a child by his wife; had to be told, when dressing, what clothes to wear and which to put on first; had to be fanned while sleeping in short cat naps every day until about noon, because of persistent insomnia; and had not visited his place of business or even paid his bills for over six months. At the table, he would chew food indefinitely until told to swallow. His demeanor was extremely apathetic, except at intervals, when he would become excited, start suddenly from his chair, seize his head in both hands, and pace the floor, exclaiming about the intense pain in his head.

Prior to his mental failure, he had suffered for twenty years with neuralgic attacks in the left eye and left side of the face, and also from flowing of tears over both cheeks in cold weather. For six years he had lived on a restricted diet on account of constipation, flatulence, gastric pain, and other symptoms of indigestion. His persistent sleeplessness added greatly to the care of this patient. He could not stand the excitement of a public hotel; hence he was forced to lodge with friends in an extremely quiet neighborhood of Brooklyn, and to come to my office daily in a carriage while I was endeavoring to get any satisfactory eye-tests. It took nearly a week to get these, because the patient became too excited and uncertain in his answers to make the tests positive at first.

The case looked most unpromising to me. I could not divest myself of the firm conviction that organic brain disease existed, and that the case was probably incurable.

I advised his wife to seriously consider the advisability of a graduated tenotomy upon the left superior rectus muscle as a step toward the correction of the 4° of "manifest hyperphoria" that the patient disclosed. I distinctly impressed upon the wife the fact that I did not think this step would prove curative; yet I could not but feel that the hyperphoria was a strain that ought to be at once removed—especially from so weak an invalid. I assured her that there was little ground for hope of recovery, but that the patient would probably have less pain and sleep better after the correction of the hyperphoria.

I mention this because the complete recovery of this patient was as much of a surprise to me as to others. The rapidity of recovery was almost beyond belief. In my professional life I have never seen anything that caused me so much astonishment in the line of prompt result from an operative procedure.

With the consent and expressed desire of his wife, I performed a graduated tenotomy upon the left superior rectus muscle. Immediately after the operation he was placed in a carriage and taken to Brooklyn.

Now came the remarkable changes to which I have previously referred as startling. The entire night following the operation he slept without awakening—a thing unknown for years. He arose the following morning, and (after dressing himself without aid) drank three goblets of milk before the rest of the family were up. He then sat down and ate a good breakfast, finishing as quickly as any of the family. Within a week he demanded his money from his wife, saying that he would not have her pay bills for him. In a very short time he came daily from Brooklyn to my office without any one to accompany him. Two weeks after the operation, he wrote a letter (the first in over four months). He began to read the daily papers, continued to sleep and eat well, and within a month almost entirely regained his mental faculties. A full correction of his refractive errors was then ordered; with instructions to wear his glasses constantly.

Some weeks later, I decided to perform a second graduated tenotomy upon the right internal rectus muscle for the relief of a latent esophoria that had disclosed itself. Soon after this operative step, the patient returned to his home in Canada.

He has been seen by me only at infrequent intervals since that time. He soon resumed control of a large business; gained over forty pounds in weight within a year; has taken no drugs; and is absolutely well to-day. There has never been a relapse of his former condition since the first operative step was taken on the left superior rectus muscle of the orbit.

At no time, for the past fifteen years, has this patient ever experienced a relapse. The relief of eye-strain effected a complete cure.

If anyone sees attractive features in tenotomies—surely this patient does!

He practically owes his life to a complete arrest of eye-strain.

Cases XV, XVI, and XVII are illustrative of the effects of tenotomies upon intense and persistent neuralgias.

The first of these was a lady from the South, who, within a period of three years, had every tooth separately extracted, in the vain hope of relief from neuralgia in the jaws. The pain was so intense as to produce complete unconsciousness for days at a time. Two tenotomies, within one month, upon the eye-muscles cured her of pain. The relief has now been permanent for over ten years.

The second of this group (Case XVI) was a young minister of the gospel, who was sent to me about thirteen years ago by the late Dr. Geo. B. Leonard, of New York City.

When he first came into my office after having been treated for facial neuralgia for over a week with morphine by the physician who referred him to me, he was nearly insane with pain. He threatened suicide if nothing could be done to arrest his suffering at once; and stated that, although a clergyman, he would not be held responsible by a just God for seeking death as a means of relief.

The instillation of an atropine solution, into the eye of the patient arrested his efforts of accommodation and gave him almost complete relief within the short space of fifteen minutes*; and at the end of one hour he was entirely free from pain,

*The effect of atropine (as a paralyzer of the accommodation) upon intense facial neuralgia is often almost miraculous; especially when hypermetropia (far-sightedness) exists and the patient is under forty years of age. I have seen facial pain arrested so frequently by the simple procedure of dropping an atropine solution (4 grains to the ounce) into the eyes during the paroxysm of neuralgia that it constitutes to-day with me one of the most satisfactory steps in the investigation and treatment of neuralgias.

smiling, and apologizing for his previous excitement and loss of control of himself.

A complete and permanent cure of this patient was made by prescribing spherical glasses, and performing two graduated tenotomies upon the internal recti muscles. He is to-day the pastor of a large church in a New England town; and has been totally free from neuralgic attacks since the tenotomies. I lately operated upon his child for a double cross-eye; evidently an inheritance from the parental side.

The third of the group (Case XVII) was one of the most persistent and aggravated instances of intense facial neuralgia that I have ever seen. I saw him first in 1888. The paroxysms would come on without apparent cause and at very frequent intervals. They would last for several days, in spite of very large doses of morphine given through a hypodermic syringe.

He was treated for some years for these attacks by a large number of the leading specialists of New York City without any relief. One of his physicians sent him to the late Dr. Loring, the famous oculist of New York, who prescribed glasses to correct about one and a half dioptres of hypermetropia and a slight degree of astigmatism. These he had worn constantly for about three years; but no appreciable benefit had been experienced from wearing them, except that he "thought he saw a little better with them." He had been for many months under the care of the late Prof. E. C. Seguin, the distinguished neurologist, who experimented upon him with almost every narcotic known. At one time, aconitia was pushed, under Dr. Seguin's personal supervision, until aconite poisoning appeared. The patient could not at one time talk plainly from the effects of this drug and the tongue and throat became almost paralyzed for several days. The intensity of the neuraliga paroxysms at times made his family fear suicide; and the patient learned to administer morphia and atropia by the syringe to himself when he felt that the attacks were getting beyond human endurance.

Throughout six or seven years of such suffering, this victim to neuralgia consulted almost every specialist of note in his vain efforts to obtain relief—but in despair over his failure, he became my patient at the solicitation of a friend who had been personally cured by eye-treatment.

On examination of this patient's eyes, I found that Dr. Loring had given him glasses that were a full correction for all his refractive errors; but like many other oculists, he had not investigated the eye-muscles, which were seriously at fault. He disclosed a very moderate degree of esophoria* at the first examination, but later on I found him to be a victim to "latent" esophoria of a high degree. Within two months, I performed a graduated tenotomy upon both interni of this patient. His neuralgia ceased entirely within a week from the date of the first operation, and he has been entirely free of neuralgia for the past fourteen years.

About two weeks ago (sixteen years after the tenotomies) this patient called upon me while in New York and stated that "his marvelous restoration to perfect health by so simple and painless an operation had been considered a miracle by his friends and family." His eye-tests showed no marked change in his refraction; except that he needed a stronger glass for close work, which was ordered. I found, however, to my delight, that the esophoria which originally existed and had caused all his suffering was completely relieved; and he left with the happy assurance that he had no reason as far as I could see to anticipate a return of his old trouble from eye-strain.

All of these three neuralgia sufferers see to-day some attractive features in tenotomies!

Each has been restored to perfect health by the relief of eye-strain.

Cases XVIII and XIX suffered for many years from extreme sleeplessness and complete nervous prostration. These two cases illustrate well the effects of tenotomies upon these distressing conditions—of which I could cite at least one hundred cases, if necessary.

The first of these cases was that of a minister of the gospel who consulted me about fifteen years ago (prior to resigning his pastorate) because of long-continued insomnia and a complete physical breakdown. He was restored to perfect health within three months by graduated tenotomies upon the external recti muscles. Since that time he has used his eyes constantly without any distress and has never suffered a relapse of his insomnia or nervous prostration.

The second of these (Case XIX) has lately come under my observation. A married woman of about 35 years, strongly built, and with no outward appearance of organic disease, was brought to my office from a Western city about two months ago.

She stated that a peculiar twitching of the muscles of her legs and feet had developed (whenever she was in the recumbent posture) within two years. While not actually painful, these twitchings prevented sleep to such an extent that she frequently sat upright in a chair wide awake an entire night. In several instances, she had done this for three consecutive nights. She had tried all forms of hypnotic drugs under medical advice without any permanent relief; and she was rapidly forming a confirmed drug habit on retiring, in the hope of obtaining sleep even for a few hours each night. She had gradually developed symptoms of nervous prostration.

I found that she had practically no refractive error; but I gave her some prismatic glasses to wear constantly because she showed excessive weakness of the external recti muscles.

Almost immediately, normal sleep returned to her. Subsequently I performed one graduated tenotomy upon the right internal rectus muscle and thus dispensed with her glasses. She seems to be completely cured of her insomnia and muscular twitchings; had gained greatly in weight and strength when I last saw her (about two weeks after the tenotomy); and in every way showed a marvelous improvement in her spirits and general facial expression.

Both of these patients, have to-day cause to see some attractive features in tenotomies!

The terrible consequences of confirmed insomnia have been averted in both instances by a painless surgical procedure.

Case XX.—Twelve years ago (May, 1892) a young lady of about 20 years of age was sent to me from Brooklyn, N. Y. to see if eye tests made by me could shed any light upon periodical attacks of extreme and uncontrollable vomiting, followed by loss of both power and sensation in both arms. These attacks would occur about every two weeks. They would either begin with numbness or pain in the head; then violent vomiting would begin and often last twenty-four hours; and with these symptoms there would develop blurring of vision, pain in both eyes, intolerance of light, and great difficulty in breathing.

After her first attack, she lost coordination of her tongue muscles; had numbness develop in both

* A tendency of the eyes to swing toward the nose.

hands and arms; and finally lost all power in both arms. This was never fully regained until after I had performed the first tenotomy upon her eye-muscles in 1892. Prior to her first visit to my office she had worn glasses for many years that fully corrected a high degree of hypermetropia with astigmatism. These she is still wearing, I imagine; as they had been judiciously prescribed.

I performed three graduated tenotomies upon her internal recti muscles soon after she came under my care, because they were imperatively indicated. Within six months after these tenotomies there was a complete restoration of health.

For the past twelve years she has never had a relapse of the old attacks of vomiting or any of her other alarming symptoms. It is reported that she has changed from a very thin delicate girl, in whom physicians had diagnosed a "tendency to consumption," into a strong and perfectly healthy woman.

This patient sees to-day some very attractive features in tenotomies!

Her rapid and complete recovery after scientific eye-treatment without the use of any drug seemed a miracle to the numerous physicians who had attended her as well as to her family and intimate friends.

General Résumé.—The twenty cases that I have selected for incorporation in this monograph illustrate the startling and curative effects that a complete relief of eye-strain by graduated tenotomies can afford to sufferers from conditions which apparently had little or no association with the eyes.

Some of these sufferers were not aware of the existence of any symptoms that had indicated to themselves or their medical advisers that the eyes were in any way abnormal.

Yet it may be well for my readers to see what varied conditions of ill-health these selected cases illustrate:

Case I.—*Asthenopia.*—Associated with repeated "physical breakdowns" (whenever study was attempted). In my work on "Eye-Strain in Health and Disease" I report (in tabulated form) many cases of this condition, usually associated with headache or neuralgia.

Case II.—*Epiphora* (of years' duration). Tenotomy arrested, at once, the flow of tears over the cheek that had persisted for years in spite of all treatment.

Case III.—*Extreme Deformity from Wry-neck.*—This case was completely and permanently cured by eye-treatment.

Cases IV., V., XI., XII. and XIII.—*Epilepsy.*—In my work on eye-strain I give tabulated records of the eye-treatment of epilepsy in 26 cases. I would also refer my readers to the *N. Y. Med. Jour.* of December 4, 1904.

Case VI.—*Insanity.*—This remarkable case is supplementary to several that I have reported in my work upon eye-strain—previously referred to.

Cases VII. and VIII.—*Nervous Prostration.*—These extreme cases of a very common result of unsuspected eye-strain, are worthy of careful perusal by those who still scoff at eye-treatment in extreme nervous derangements.

Case IX.—*Chorea—followed by Paralysis.*—The history of this case had led to a positive diagnosis of brain-tremor by a neurologist of international repute.

Case X.—*Progressive Atropy of Muscles in Both Hands; Partial Loss of Use of Right Hand; Diabetes (of some years' standing).* This remarkable case illustrates the results of eye-strain upon the activity of spinal cells, and also its influence as a factor in causing diabetes.

Case XIV.—*Complete Loss of the Intellectual Faculties.*—This startling case has no parallel in my professional experience; yet the relief of eye-strain effected a complete and permanent cure.

Cases XV., XVI., and XVII.—*Uncontrollable Neuralgia.*—These three cases were selected for publication here because they were remarkable for the persistence and severity of pain. My book contains full details of all treatment of many similar cases.

Cases XVIII. and XIX.—*Sleeplessness and Nervous Prostration.*—These two cases are selected to illustrate the relationship between unsuspected eye-strain and two very common types of extreme suffering from insomnia. My book contains a chapter upon insomnia and its treatment, with many illustrative cases.

Case XX.—*Uncontrollable Attacks of Vomiting; Loss of power and Sensation in Both Arms; Suspected Tuberculosis.*—This case was a puzzle to many medical men, until eye-strain was completely relieved by tenotomies. A full correction of refractive errors (by glasses) had been tried without any beneficial results.

Some Clinical Suggestions Relating to the Cause of Obscure Nervous Derangements.—In bringing this contribution to medical science to a close, I offer the following suggestions to those physicians who are as yet apathetic to or prejudiced against one of the greatest discoveries of this century, in its relation to the arrest and permanent cure of many types of physical suffering.

One of the many converts to the theories that I have for over twenty years expounded and fought for (against bitter professional antagonism in the past), strikes an important keynote in a late contribution to this field* when he says:

"The laity have an idea that physicians ought to know all about every new theory that comes up, and value the opinion of physicians accordingly. If a physician is asked his opinion of a theory that he has not considered it worth while to look into, the chances are he will say there is nothing in it. What is his opinion worth? asks the layman. Nothing!"

Again, physicians and interested friends often tell patients upon whom a tenotomy ought to be performed, that the "operation will ruin their eyes." Case No. 1 of this article illustrates this point.

Such gratuitous and ill-timed advice often delays or indefinitely postpones the commencement of a recovery.

The views which many years of experience in this special line of ophthalmology have led me to advocate are as follows:

(1) It is vitally important and essential to success that the *refractive errors* of all patients be positively determined.

(2) A mydriatic is usually required to make such information absolutely accurate.

(3) All refractive errors should be intelligently corrected by glasses. These should be *worn constantly* for a length of time sufficient to determine if they modify any apparent muscular anomalies in the orbit.

(4) *A tenotomy upon an eye-muscle should never be suggested or performed too hastily.*

It often takes considerable time to determine if the full correction of refractive errors by proper glasses is not all that may be required to effect a cure.

Those who have the largest experience in this field are often the slowest to operate. Yet, in the twenty cases reported here, tenotomies were most positively indicated and were, therefore, performed by me.

* Dr. F. D. W. Bates, *N. Y. Med. Jour.*, Dec. 24, 1904.

(5)) In searching for anomalies of the ocular muscles, it is vitally important not to be *misled into accepting the records of the first tests* made upon any patient's eye-muscles as a basis for final conclusions or positive advice.

It may be the "latent" or hidden muscular errors (which the patient has unconsciously learned to overcome, after years of practice, by various "tricks of adjustment), that are sapping the nervous vitality of this patient, because of the excessive nervous expenditure so entailed.

(6) The mistake of not ascertaining the "latent" muscular errors* of the orbit by a judicious and methodical use of prismatic glasses for the purposes of diagnosis, perhaps accounts for the failure of many oculists (not thoroughly familiar with modern methods), in solving complex eye-problems.

(7) It takes much patience, together with careful and repeated observations of some patients, to ascertain positively what are the indications for scientific eye-treatment, and which step should be taken first.

The physician who wrote to me some years ago that "he had read some articles of mine on the treatment of epilepsy—and that he was tempted to cut some eye muscle in an epileptic patient to see if it did any good"—left me in doubt whether to feel ashamed of his intelligence or of my personal presentation of so complicated a field of diagnosis and surgery.

(8) The utterly absurd claim that has too often been made in the past, and which has been loudly asserted again, of late, by one or two enthusiastic and prolific writers, viz., that "eye-strain is always due to errors of refraction," does not, in my opinion, merit to-day any serious attempt at contradiction. Such people see but one-half of a great field in curative medicine.

The cases reported in this article afford ample evidence to the *absurdity* of such statements.

(9) Refractive errors may cause "apparent" heterophoria† in a certain proportion of cases; and properly prescribed glasses may sometimes modify "genuine" heterophoria.

(10) Genuine heterophoria* may co-exist with refractive errors; and it may also be found in cases where absolutely perfect refraction exists.

(11) The cases reported here demonstrate that eye-strain may unquestionably be a factor in causing extreme and persistent nervous derangements of widely different types.

(12) Some of the cases reported here ought to convince the most confirmed skeptic that it is an imperative step to look for eye-strain first by modern methods, and with modern instruments, before obscure nervous derangements are diagnosed as organic or an unfavorable prognosis given.

(13) Some of the cases reported here show that even neurologists of repute and large experience cannot always tell an organic disease of the nerve-centers from a condition that may be due to eye-strain and be curable by giving nature a chance through the removal of its exciting cause. See Cases III., IV., V., VII., VIII., IX., X., XI., XII., XIV., and XVII.

(14) Several of the cases reported here demonstrate most positively the direct relationship between eye-strain and convulsive attacks.

(15) The intimate connection between eye-strain and intense pain is well shown in cases XV., XVI., and XVII.

It is my firm conviction that no case of headache or neuralgia is scientifically treated to-day until scientific tests are made upon the eyes by modern methods, and modern instruments.

The percentage of eye-strain in cases of persistent headache and neuralgia is enormous.

(16) The extremely conservative views embodied in the preceding conclusions are of great value in treating eye-strain; yet experience often brings us face to face with certain eye-conditions that imperatively demand prompt and complete relief through graduated tenotomies.

In all cases of "genuine" heterophoria the only way to obtain the best results is to radically remove the muscular errors either by tenotomies upon the abnormally tense muscles, or advancement of the muscles that show defective power.

(17) I positively condemn the methods that are employed to-day by some oculists with a view of training abnormally weak muscles (by long continued use of prisms) to overcome and thus mask a congenital defect of muscular equilibrium in the orbits—which is evidenced in "genuine" heterophoria.

(18) The daily exercising of the ocular muscles by prisms for a few minutes at a time, (with the object of strengthening all of the weak muscle) may often help patients that suffer from asthenopia*; but this procedure never cures "genuine" heterophoria, nor does it accomplish what a tenotomy will, when imperatively demanded, and skillfully performed.

(19) I condemn the prescribing of prismatic glasses for long-continued and constant wear; as a substitute for tenotomy, as a means of cure in marked cases of "genuine" heterophoria.

The prescribing of a sustaining splint or a crutch might possibly enable some patient (with a diseased joint) to walk, and afford him temporary relief; but such appliances do not cure a diseased joint, or rectify a congenital deformity.

Prismatic glasses are often of great utility to an oculist in making a diagnosis of "latent" heterophoria; and they often enable him to temporarily relieve or arrest some symptoms caused by eye-strain. Yet the tenotomy will usually accomplish still better and more permanent results in cases where "genuine" heterophoria is producing extreme physical ills; and with much less annoyance to the sufferer than a thraldom to prismatic glasses entails.

(20) It is both unjust and untrue for physicians or oculists to assert (as they often do without personal knowledge of the facts) that graduated tenotomies upon the eye-muscles (when imperatively indicated, and skillfully performed) "will ruin the eyes," or words to that effect.

I have personally had two tenotomies done upon my own eyes with immediate and marked benefits; have performed three tenotomies upon my only child with most satisfactory results; have operated for "genuine" heterophoria upon many hundreds of eyes for various types of physical ills induced by eye-strain; and I know that I have had a larger percentage of good results, and fewer annoyances to the patient after these operations, than in any line of operative surgery that exists to-day.

Thanks to modern methods and greater care in developing latent heterophoria prior to operation, over-corrections have been extremely rare experiences with me during the past fifteen years.

Even a marked over-correction (should it occur)

*One chapter in my book "Eye-Strain in Health and Disease" is devoted exclusively to the modern methods of testing the eyes.

[illegible] within the orbit.

*A term that covers an inability to use the eyes without pain.

can easily be rectified by an advancement; and I have never seen (in my experience of over twenty years in this work) a single instance where the acuteness of vision has been impaired to the slightest degree by a graduated tenotomy. On the contrary, I have seen many cases who have had the acuteness of vision greatly improved after the eye-muscles were properly adjusted. I have on record a few instances where astigmatism has apparently been cured by tenotomies.

(21) Graduated tenotomies upon the eye-muscles are performed by me to-day under the influence of cocaine and adrenalin (suprarenal extract).

The first makes the operation painless; the second almost totally arrests any hemorrhage.

A painless and bloodless operation that may dispense with the use of glasses (in some instances) and in many cases effect an immediate cure of extreme physical suffering, ought not to be condemned from pure prejudice or ignorance, nor distorted into a step of untold dangers to vision and health.

345 Madison Avenue

ON SOME RELATIONS OF MEDICINE AND SURGERY TO JURISPRUDENCE.*

By CARL BECK, M.D.,

Professor of Surgery in the New York Post-Graduate Medical School and Hospital, Visiting Surgeon to the St. Mark's Hospital and the German Poliklinik

In accordance with the customary program of our Society the pleasant service of addressing you to-night falls to my lot. A pleasant service, indeed, because I have to congratulate the Society on its successful history, and to indulge in audacious anticipations for its future.

The *raison d'être* of the Society of Medical Jurisprudence is mainly the mutual benefit which medicine and jurisprudence derive from each other. Great as this benefit is, it is too little appreciated. It seems to me that the neglect is especially on the part of our medical friends. I shall regard it as the most stringent feature of my term of service to impress my confrères with the necessity of becoming better acquainted with legal points, not only for their own benefit, but in the interest of humanity and justice.

The medical profession is called a noble one, because it is expected to, and does, treat the poor free of charge without grumbling, and that though this largesse is often abused. Physicians in fact commit professional suicide in laboring to exterminate the diseases which give them the means of living. They are doing to-day what was only hoped for by no less a man than Bacon, who said: "I have hope and wish that the nobler sort of physicians will advance their thoughts, and not employ their time wholly in the sordidness of cures; neither be honored for necessity only; but that they will become coadjutors and instruments of the divine omnipotence and clemency in prolonging and renewing the life of man."

But noble as the members of this profession are, they are apt to neglect their duties as citizens as far as they are not of a hygienic character, and their indifference to legal points is one of their most conspicuous sins of omission in this direction. It is even a fact that most physicians do not know how far they are responsible to their patients. They believe in general that honesty and common sense are guides sufficiently reliable to serve as mentors in practice, and therefore do not realize that sometimes even the best intentions violate the law. *Summum jus, summa injuria!* is still true in our modern times. This the physician should keep in mind, especially for his own sake.

It is by no means always easy to define accurately what the physician's responsibility is. It varies with the nations, with the times, and with the scientific fashions. Schiller's words: *"Das Ewigdauernde ist nur der Wechsel"* ("The only lasting thing is change") preeminently apply here. How strange that the Roman Haruspices were regarded to be infallible, although the misera plebs used to say: *"Haruspex haruspicem cum vidisset, risum tenere non potuit."* The same plebs which ridiculed these fakirs was ordered by law to believe their doctrines. Egyptian physicians risked corporal punishment when they overstepped their well-established Codex. The warriors of Alaric the Goth turned the unsuccessful surgeon over to the relatives of the patient who had succumbed while under his treatment.

Modern times treat the physician somewhat more leniently. The majority is well aware of the great advances medical science has made since those dark days, and is inclined to transfer its respectful appreciation to the person of the physician. Still it cannot be denied that among some classes this respect is severely lacking and some people know of no better amusement than to make jokes on their medical adviser. In each weekly issue of the *Fliegende Blaetter* there is at least one joke on the doctor, as a rule of a harmless nature. But our *Life* is hard. This excellent satirical weekly would deserve our full admiration did it not always find something about the vermiform appendix which is meant to show the surgeon in an absurd, if not a dishonest light.

Such prejudices, while ordinarily not intended to do any harm, may turn sometimes to the disadvantage of physician as well as of patient, and assume a severe physiognomy when exploited among ignorant jurymen.

There is some truth in the Jeremiade of Buxton: "If you talk with the average juryman, he will tell you the doctor is rich, the doctor has an easy time, doesn't have to work, just rides about, makes his money easily, has a good home, good clothes and a good time in general. He will tell you the doctor can get along without what little he owes him, the doctor doesn't need it. This average juryman cannot enter into or appreciate the peculiar trials, anxieties, and exacting duties that fall to the lot of that same overworked doctor, who is still plodding on, Sundays and holidays, not able to complete his arduous duties in eight, ten or twelve hours, but is still watching patiently by the sufferer's bedside, it may be all night, while the envious juryman lies snoring in bed." This standpoint is not general, but still widely spread. It is a strange and non-explained phenomenon that the same man is viewed in this way who spends his life merely for the benefit of others, gives his services to public and private charities for years, exposes himself at all hours and in all kinds of weather to disease, danger, and death; spends his time with the unhappy, the discouraged, and despondent, brings them in exchange for their long tale of woe, encouragement and hope for better things; but in return for these hard tasks—dirty, disagreeable, unsavory jobs—receiving little remuneration or none whatever.

These lamentations are somewhat exaggerated, but much of them is true. Still, in the pursuit of our professional duties, we have no right to take sentimental views. We must face all these disagreeable facts with the eye of the altruistic philosopher and assume that attitude in our relations which has its best fundament in the understanding the laws of our own country. Now, what does the law say?

In the first place, the law does not require omni-

* Presidential address delivered before the Society of Medical Jurisprudence, January 9, 1905.

science, or hold the physician liable for any and every error of judgment. It only requires that a physician should possess a reasonable degree of learning and skill, and exercise, according to his best judgment, reasonable and ordinary care and diligence. It appreciates fully that, as none of us is infallible, a degree of responsibility exceeding these limits would virtually debar us from the exercise of our profession, and would therefore soon deprive the public of all medical aid. The physician is, for instance, not responsible for the deleterious or fatal effect which results from the administration of chloroform as an anesthetizing agent to an individual of a peculiar constitution or idiosyncrasy, the nature of which could not be known to him before the administration. But if such administration was not preceded by a careful physical examination, or was made in an improper—say upright position (except there should be some exceptional reason for it)—or if there were no means of resuscitation at hand, the physician would be guilty of malpractice. If the outcome was fatal he may be indicted for manslaughter.

The same applies to operative surgery, the surgeon being expected to possess ordinary skill and knowledge. Still, dissatisfaction with the result, especially the unfortunate outcome of a surgical operation, frequently furnishes a basis for a suit for damages. It is hard to please everybody; and while the surgeon sometimes regards the result of his operation as extremely beautiful, the patient may hold a strictly opposite view.

B. von Langenbeck, my revered teacher, was regarded the master of plastic surgery in his time. The results of his rhinoplastic operations were admired the world over. Once he transplanted a skin-flap from the arm of a young man whose nose had been destroyed by an ulcerative process, and after forming the nostrils he was so much impressed with the beauty of the result, that he gave expression to his pride by showing it to the patient in a mirror. But no sooner had the "grateful" patient seen his new facial prominence than, in his great disappointment, he threw the mirror in the face of von Langenbeck.

I had a less "striking" experience with a charity patient, for the gangrenous stump of whose thumb I found a substitute, which permitted the continuation of his profession. This would have been impossible had I pursued the ordinary way of simply amputating the stump. I presented the case to a medical society in whose Transactions the result was called "excellent." But the patient, instead of realizing that he should have been grateful to me, said that he had been exposed to some inconveniences during the tedious course of treatment, for which $100,000 from my pocket would be a fair equivalent.

Such experience is somewhat like that of the rescuer, who was bombarded with rotten eggs by the boy from whose scalp he pulled out a few hairs while saving him from drowning.

Of course, the surgeon has to be careful, and when great operative risks are to be anticipated, they should be explained thoroughly to the patient in the presence of a witness. Of course, an action can be commenced in spite of all precautions, but the plaintiff could never recover under such circumstances.

Especially if experiments are undertaken, the surgeon must be on his guard. In former years it was decided that if an experiment on man was followed by injury or death, the experimenter should be culpable. But tempora mutantur. A surgeon who can show good reasons for a new procedure, especially when a simple operative method has failed to relieve his patient, cannot be held responsible for an unfortunate outcome of his experiment. Of course, as alluded to, the patient or his relatives must have given permission.

It seems to be somewhat unjust that, the higher the standing of a physician is, the more skill should be expected from him, in other words, his failures should be condemned the more severely; while the Christian Scientist, the farrier and the quack are but seldom prosecuted for their failures. The views, which, according to Puffendorf, the Mahomedan Justice held, when a blind man brought suit against a horse doctor, may also be approved to-day. The unfortunate patient attributed his fate to an eye-salve which the quack usually applied to his equine patients. But the oriental Daniel dismissed the complaint on the ground that if the patient had not been an ass himself, he would not have consulted a horse-doctor.

There is a great deal of common sense in this decision, but is it just that the ignoramus should escape by virtue of his ignorance? Is it not dangerous to set the quack or Christian Scientist free because their treatment may not do any positive harm, while it consumes the valuable period during which, as in cases of appendicitis, strangulated hernia, placenta prævia or hemorrhage from a divided blood-vessel, it would have been possible to save the life of the patient?

What is meant by "reasonable skill and knowledge?" There is difficulty in answering this question; for there are few methods in the use of which all authorities agree. There are, however, certain established principles which must be adhered to, while the method of their special exercise may vary according to the different scientific standpoints. A surgeon, for instance, who nowadays should proceed to operate without any aseptic precautions, would be condemned by his confrères. But whether he would prefer to render instruments and skin sterile by the mechanical means of cleanliness, viz., soap and water, or by chemical methods, maintaining that the chemical action was of a stronger bactericidal power, should be left to his own discretion. His special modus operandi must also be influenced by the peculiar conditions arising from the environment of the patient. Under extraordinary circumstances (battlefield, railroad accident, prairie) he may also be compelled to employ an unskilled or non-medical person as an anesthetist, in which case it would be unjust to add to his great responsibilities that of the anesthesia. As a rule, it is highly imprudent to operate without the assistance of at least one qualified practitioner, wherefore such risks should be taken under the most pressing circumstances only.

The most fertile field for the great army of the disappointed are the various complications and sequelæ occurring in the course of the treatment of fractures. Whenever there is deformity or shortening, the patient and his friend enjoy claiming that the surgeon's art was defective, although there may have been circumstances which were beyond his control. And nothing hurts the reputation of the practitioner more than a badly healed fracture—it will tell an endless story. Twice it has been my privilege to demonstrate the importance of this great subject before our Society, especially in connection with proofs of the usefulness of the Roentgen method, the admirable medium which brought about a complete revolution of the science of fractures. The many unfortunate circumstances, which so often prevented the surgeon from making an exact diagnosis, thereby causing the much-dreaded deformities, have ceased now to hang like the sword of Damocles over the surgeon. Accurate knowledge has taken the place of ignorance, and doubt and painful

manipulations are no longer a necessity for diagnostic purposes.

Even the most skilful experts in fractures have ceased to deny that there is an enormous number of bone-injuries, which, in former years, could not be properly recognized, the general symptoms being either obscure or veiled by the swelling of the surrounding tissues. The mistakes made in trying to differentiate fractures from dislocations, contusions, distortions or tumefactions were innumerable; but they could be proven as such only under extraordinary circumstances. Now, with the aid of the rays, we can see the conditions as they are, and the rays are, in fact, impolite enough to do this without the slightest regard for great authorities. No wonder that such brusque information has been received with a feeling of uneasiness, often by the very men who should have been but too glad to learn of their diagnostic errors, in order to correct them, as long as there is time.

And as long as there is time, the Röntgen method is the faithful friend and adviser. It unveils the truth in its awesome nudity. The advice of the sometimes burdensome, but always reliable friend should be followed and his warnings listened to, because if done in time, much disaster may be averted. The same friend will become the formidable prosecutor, if the truth is disclosed after the chances for proper correction have waned.

In former years it was customary in the face of an obscure case, to assume an extremely wise attitude and sigh: "If we could only look through it!" Now, since this wish has become a reality beyond our most audacious expectations, there are still many who think that by virtue of their peculiarly well developed palpatory talents they could diagnosticate fractures just as well. Such arrogance will find its punishment in the court room some day, for judges and lawyers now begin to take thorough interest in the new method.

Is it right to risk an experiment, when a simple glance with the fluoroscope furnishes the most precise evidence—when it can at once be clearly determined whether there is comminution or impaction, or intervention of muscular tissue, or intraarticular fracture, or association with dislocation?

It is a blessing that if the picture is fixed on a photographic plate, the nature of the injury can be studied at leisure, and the proper line of treatment decided upon without subjecting the patient to any tentative manipulations. After a dressing is applied the fluoroscope or the Röntgen plate shows whether the fragments are in position or not. If they are not, the dressing is removed and the false position corrected at once. In this manner the execution of all therapeutic measures can be verified by the Röntgen guide; the dressing itself, even if consisting of plaster-of-paris, offering no obstacle to the rays, so that the position of the broken fragments can be controlled through the dressing. Thus the therapy is enormously simplified and perfected, the Röntgen mentor always showing the true nature of conditions.

It is evident that at the early stages the Röntgen rays are the friend of the physician. Not only do they advise him as to the course of treatment, but they are also a medicolegal document which may show that the injury was of an extraordinarily severe character, so that perfect restoration is an impossibility. Only a fool would, in the face of a shattered bone-epiphysis, expect that recovery should take place without deformity or disturbance of function.

Cripples usually live long, so that they may have many chances to annoy the surgeon if they, as it often happens, are of a virulent temper. Shakespere, the greatest seer into the depths of the human heart, has disclosed this weakness in the matchless monologue of the deformed Gloster, who laments:

> I am not shaped for sportive tricks,
> Nor made to court an amorous looking-glass,
> Have no delight to pass away the time,
> Unless to spy my shadow in the sun
> And descant on mine own deformity:
> . . . . curtailed of this fair proportion
> Cheated of features by dissembling nature,
> Deformed, unfinished . . scarce half made up
> And that so lamely and unfashionable,
> That dogs bark at me, as I halt by them.

But besides the medicolegal points referring to himself, the physician should know how to give testimony about diseases or injuries treated by him or a confrère, from a strictly medicolegal point of view. Every physician, just like everybody else, is liable to be subpœnaed as an ordinary witness, when he, for instance, observed somebody run over by a trolley car or saw a man knock down another. But if he happened to treat the injured professionally, the prosecutor or the defense may wish to obtain his professional testimony in the case. This will not only give him a splendid opportunity to perfect him in practice, but will also lead to professional preferment. It also entitles him to extra compensation, and he cannot be compelled by a hostile attorney to testify contrary to his desire, as his opinion is his own property.

Such opportunities are extremely frequent to-day, and our knowledge of diseases induced by physical injury has remarkably increased during the last decade. Most of this great progress is also due to the Röntgen rays, many doctrines formerly regarded as incontrovertible being completely changed now. In proportion to increased anatomical knowledge, our clinical experience has profited, and thus our diagnostic and therapeutic horizon become much widened. If we consider the simple fact that the annual statistics of the railroads of the United States alone show 4,000 persons killed and 38,000 injured, and that German statistics say that in 1898 more than 97,000 workmen insured under the German law were injured in some way, the immense importance of the subject from a medicolegal point of view is evident. It is obvious that by far the greater majority of the cases is brought before the courts, and who else is able to judge the extent of the injury and its consequences, and also its significance for the commonwealth, if the physician is not?

I am told by one of my friends of the bar that one-half of all jury trials in New York are for personal injuries. This speaks loudly enough. Of course, the working classes are more exposed to injuries than the wealthy, and for them the question of an injury oftentimes means "to be or not to be." It is natural that a jury in this country is inclined to favor the poor workman, being guided by sentimentality and not by the cool considerations of jurisprudence. The new laws of Germany have practically eliminated this emotional factor. So far Germany is the only country which by its law insuring workingmen against injury (*Unfallversicherungsgesetz*) has succeeded in giving protection to the workmen who expose themselves to danger in their various occupations. One of its paragraphs provides as follows: Workingmen and employees, excepting those of commercial, domestic or a few other callings, whose annual wages do not exceed the amount of $500, are insured against accidents incident to their various occupations. Such persons who are injured while at their work are all entitled to free medical attendance, and from the fourteenth week after the accident, to an indemnity of two-thirds of their wages.

In the event of death, the widow of the workman is entitled to burial expenses and to full indemnity for herself and her children until the latter reach the age of fifteen years. The amount of indemnity is based on medical testimony throughout. The indemnity is graded according to the disability. If it should happen to be total, the full amount is paid out; if partial, only a fraction of the amount is granted. If he is disabled for his special work, but can support himself, though much less, at some other occupation, payments are then made proportional to his decreased earning capacity.

One of the predominating features of an injury case in this country is the question of negligence on the part of the employer. In most cases this forms in fact the salient point. In Germany this factor is left out altogether, the employer and the employee being treated with equal justice. The medical expert will therefore not be embarrassed, since there is no exaggeration on the part of the injured. In this country it does not too rarely happen that the injured plaintiff appears like a disfigured Richard III before trial, while after he obtained his money he will walk as erect as others. In Germany, as illustrated by me in the case of a refined malingerer (see my paper on "The Medicolegal Value of the Röntgen Rays," *Medical Record*, August 9th, 1902), a new action may be begun after there is some reasonable suspicion of unfair play.

In this country simulation is very little practiced, but exaggeration is so much more commonly found. To disrobe a case from exaggerations and represent it truthfully is extremely difficult. In order to do justice to the case as well as to himself, the physician must strictly adhere to scientific points and not be influenced or tempted by exterior considerations.

A fractured leg or a bullet in the thigh cannot be simulated, but a fracture may have healed as far as the bones are concerned, and no visible signs may be left to be detected, even by the Röntgen method, after several months have elapsed since the injury. And still there may have been peculiar injuries of the soft tissues caused by the fracture fragments which deprive the patient from some function. Or the bullet may be extracted, but the shot-canal cannot be obliterated, and the patient will become the victim of disturbances which are of a subjective nature, and can therefore not be tested by objective methods.

It is possible to show the evidence of a fracture many years after its occurrence, if there was well-marked displacement. No fracture-line will, of course, show after that time, but the deformed appearance of the bones will present sufficient evidence of the nature of the injury.

A complicated medicolegal question will also arise when chronic diseases like osteitis, arthritis deformans or malignant growths develop after an injury. There may be no causal connection between the injury and the disease, but when an injury has happened in a factory, the indication of the patient to sue for damages is manifest. No doubt an injury often gives the impetus to the development of such diseases. The amount of damages will depend upon the duration of the healing process then, and the degree of functional disturbance. This will vary greatly, as from a simple fracture, which may be accurately united in a few weeks, to an injury followed by the development of a malignant growth, which will finally lead to the death of the patient.

As to inflammatory processes, I may refer to the case of a workman of fifty-four years, demonstrated before you nearly four years ago, who had sustained an injury of his elbow when forty years old. He had assumed at the time that there was a fracture of the elbow. Recovery took place after months, and finally the elbow remained stiff. Several years after the injury was sustained inflammatory signs had manifested themselves from time to time. They were regarded as rheumatic. But no other joints were involved. Examination eleven years after the injury showed a very much thickened elbow, which was fixed in a sharp angle. Pressure below the joint caused intense pain. Crepitus, so often found in old arthritic processes, could not be produced in this instance, as the joint permitted no motion at all. There were no indications of tuberculosis, syphilis or gonorrhea.

A Röntgen examination revealed the presence of malunion (lateral displacement) of the coronoid process of the ulna. This most probably had given the first impetus for the development of the arthritis deformans, which the Röntgen plate showed well marked in the external condyle of the humerus, while the left condyle showed entire synostosis with the olecranon process. An operation consisting in the removal of the projecting fragment by the chisel, separation of adhesions, and the partial resection of the external condyle, the seat of predilection for the acute attacks, were advised as therapeutic means. So far this advice was not obeyed by the patient, whose elbow is still stiff, and can hardly earn a living.

At the time the poor workman sustained the fracture in a factory it was supposed that he could use his arm again about a month after the accident. He had never shown any signs of ill health before. After ten weeks he was able to resume light work; then the swelling increased gradually, and the diagnosis of arthritis was made. He might have claimed damages at the time, the Röntgen rays then being able to show integrity of the tissues on one hand, and the presence of a fracture line on the other. But later, when the presence of arthritis veiled the original conditions, the workman realized that he could not prove his claim.

Under such circumstances even the Röntgen rays do not furnish sufficient light for the decision as to what was the etiological factor.

Similar views apply to the development of malignant growths after an injury. In a paper read before this society I was able to show the faint outlines of bone-shell in the soft myelosarcoma of a woman of twenty-eight years, who had fallen on her hand in dorsal flexion. The swelling resulting from it gave the impression that a fracture of the lower end of the radius was sustained. Three months after the injury, when seeing the patient for the first time, I noticed an insignificant deformity, just as it is observed in malunion of this classical fracture; still there was one strange symptom, viz., the consistency of the epiphyseal end was soft. The Röntgen picture failed to show the evidence of bone tissue, only a small remnant being left at the outer aspect of the radius. Resection was finally performed, thus proving the correctness of the diagnosis. In this case the causal connection between injury and growth was probable, but not absolutely certain. So the opinion of the medical expert would be left *in suspenso*.

In a number of cases of osteosarcoma of the shoulder observed by me, there was always a history of a preceding injury. In every case a suit for damages was considered by the more or less unscrupulous patients or their relatives, which placed me in an embarrassing position.

Another great difficulty in recognizing the etiological factor is found in the wide field of the so-called traumatic neuroses. Here it should be realized that we must rely more on the honesty of the report of the patient than on anatomical and clinical observation. Epileptiform attacks and pare-

sis are also often traced back to injuries, and it is impossible sometimes for the physician to determine whether an injury was not simply an exciting cause for the manifestation of a disease which had existed before in a more or less latent stage.

In conclusion I may say that the physician must not only recognize the injury and its consequence, *per se,* but must also know the patient himself and the kind of work which he used to do, and from the continuation of which a special injury may prevent him. So, for instance, may the fracture of that insignificant bone called metacarpus mean nothing for a bricklayer, while by the same injury a young, talented violinist may lose his chance to become a second Paganini.

These few points may illustrate that the most precise scientific knowledge alone will not be sufficient for passing just medical judgment, but it must go hand in hand with two factors which are, it is true, unscientific, but of equal importance, namely, common sense and absolute self-control.

CHOICE OF A GENERAL ANESTHETIC AND SELECTION OF METHOD OF ADMINISTRATION.

By VICTOR C. PEDERSEN, A.M., M.D.,

ANESTHETIST TO THE MEDICAL SCHOOL AND HOSPITAL.

THE subject of this paper in detail comprises only general anesthetics, for the reason that cocaine and other local anesthetics occupy a widely different field, and may be dismissed for our purposes by saying that they are valuable whenever it is impossible or inadvised to use general anesthetics. The term, general anesthetics, implies any standard drug, of which ether, chloroform and nitrous oxide are the most reliable and most familiar, or any combination or mixture of such drugs, of which the best illustrations are the alcohol-chloroform-ether, or the chloroform-ether mixture, briefly called A. C. E. and C. E. mixtures, respectively. The term may also embrace sequences or successions of anesthetics, of which the nitrous-oxide-ether sequence is the best known. One may regard the method of administration as denoting that procedure or those procedures by which a stated anesthetic, combination of anesthetics or sequence of anesthetics is exhibited, consequently, there are recognized as to ether the open, semiopen, and close methods of administration. When the apparatus of a certain authority is applied, the technique is also called method; for example: Bennett's method of nitrous oxide-ether administration. The established general anesthetics are as just stated, nitrous oxide, ether, and chloroform. Ethyl chloride is the last member of the group, and at the present time appears to merit definite recognition as such. The proportionate parts of the established anesthetic mixtures are for alcohol-chloroform-ether, one part of alcohol, two parts of chloroform and three parts of ether, and for chloroform-ether, two parts of chloroform and three of ether, as a rule, although the amount of either may be increased according to indication.

The accepted anesthetic sequences are at this moment, so far as ether is concerned, nitrous oxide-ether; A. C. E.—ether; C. E.—ether; chloroform-ether; and ethyl chloride-ether. The sequences for chloroform are ether-chloroform; nitrous oxide-ether-chloroform; A. C. E—ether-chloroform; C. E.—ether-chloroform; A.C.E.—chloroform; and ethyl chloride-ether-chloroform.

It is to be noted that one never uses nitrous oxide-chloroform as a sequence for the reason that it is unsafe to pass from a general anesthetic of high tension, namely nitrous oxide, to one of low tension, such as chloroform.

Having thus enumerated the various basic principles, the question of the selection of anesthetics or combination of anesthetics or seqence of anesthetics is reached, and one recognizes that this may comprise the elements, first, of selection for common practice; second, of choice for specific types of patient, and third, of election for definite operations.

In the selection of general anesthetics for day-to-day use, the question of safety alone is the primary point as to which it is recognized that nitrous oxide is the safest known anesthetic, especially when administered with oxygen. Ethyl chloride appears to promise rivalry with nitrous oxide in this connection, but its employment is too recent to warrant a fixed statement concerning it at the present time. Ether is the next safest, and perhaps when the length and severity of ether operations is compared with those of operations suitable for the preceding two anesthetics, ether is the safest of all anesthetics. With regard to a comparison between ether and chloroform, one should recognize the two facts that deaths under chloroform outnumber those under ether about five to one, and that chloroform is about five times more powerful than ether, since one ounce of it will carry the average patient as long or longer than will five ounces of ether, thus indicating fairly well that the statistics as to fatalities are probably correct and have a basis in this fact. The overwhelming majority of surgeons, who for many years have used all kinds of anesthetics, are against chloroform and in favor of ether. The generally accepted grounds are that ether primarily stimulates both cardiac and respiratory centers; primarily prevents depression of the circulation either by overdose or other cause; primarily corrects those factors which under chloroform so suddenly depress the heart; primarily makes less hazardous than chloroform, all changes in posture, especially from the supine to the sitting; primarily makes vomiting less apt to be followed by syncope; primarily renders moderate deprivation of air advisable, whereas under chloroform such is dangerous; primarily renders the grave circulatory reflexes unlikely, which are always imminent under chloroform. Ether primarily stimulates and accelerates respiration, changes in which are readily detected. Chloroform respiration may be inaudible and suddenly cease, especially if the posture of the patient is changed. Patients with comparatively normal health take ether almost free of risk, whereas very many chloroform deaths have occurred in precisely this class of patient. What Hewitt calls the workable area of ether is great, that of chloroform small, which means that the exactly proper quantity of anesthetic for each case is almost impossible to reach unerringly, and that overdose or underdose with ether is comparatively safe, while with chloroform either is highly hazardous. Ether poisoning may occur, leaving the circulation quite unaffected whereas chloroform primarily paralyzes the heart. These comparisons are made with the understanding that an equal amount of care is present in applying either the ether or the chloroform. Chloroform, on the other hand, is more readily administered; because more powerful, less of the drug is used per patient. It evaporates more

* Read before the Rockland County Medical Association, November, 1904.

slowly than ether, and is therefore more suitable for hot climates and high elevations. It is less bulky than ether, and is therefore more convenient for the battlefield.

The various mixtures of chloroform and ether previously spoken of occupy a position midway as to safety between the two drugs themselves. The higher the percentage of chloroform a mixture contains the greater the relative dangers thereof. The character of the anesthesia is practically that of chloroform slightly modified by the ether element present, especially as to the pulse which shows the stimulation of the ether.

The considerations which cover the selection of a general anesthetic for a particular patient comprise the following heads:

1. General State of the Patient.—Good health and absence of visceral diseases do not guarantee a featureless anesthesia, as Hewitt says, although most operators think otherwise erroneously. Feeble health usually means perfect susceptibility, and hence in these persons the cause of trouble is much less and the anesthesia far more apt to be featureless.

2. Sex and Age.—Females are better subjects than males because they are less intemperate, more susceptible to all drugs, and on the whole more courageous in sickness and more willing to do what is required of them by the anesthetist. The years of age count for less than do the diseases present at different periods of life in influencing anesthesia. Infants and young children may take ether drop by drop. Hewitt reports the case of a six-day-old child who took ether in this manner perfectly for a rather protracted operation. For infants C. E.-ether or A. C. E.-ether is a very good sequence. During the stage of crying and struggling chloroform should be given very deliberately lest the deep inspirations lead to overdose. All children bear asphyxia poorly, and hence react unfavorably to nitrous oxide gas.

In advanced life, if the lungs and heart are free of progressing disease, the choice is much the same. As a rule, nitrous oxide-ether is not the best sequence for these patients. C. E.-ether is in the minds of many a preferable combination; the writer, however, has never experienced any difficulty with the gas-ether technique.

3. Temperament.—Naturally the placid are the best, while the nervous and hysterical are the least desirable subjects. Anesthesia of the cornea in the hysterical may deceive the anesthetist as to the degree of narcosis present.

4. Habits.—Alcoholism is the most important, and invariably renders the subject combative and resistant to the drug. Hewitt states that he once gave 5½ ounces of chloroform in seventy-five minutes to a 56-year-old man, whereas the majority of subjects require an ounce or less per hour. Nitrous oxide will not anesthetize an alcoholic, but may destroy pain. Morphinism usually makes less anesthetic necessary, but in marked cases may reverse this effect and produce a long train of undesirable nervous phenomena. The tobacco habit is an important one because it renders the upper air passages chronically inflamed. Such subjects always have loud stertor and much bronchorrhea. Previous anesthesias are important only with regard to the condition of the patient at the time. If the subject is anemic they play no part; if robust, they may be followed by great resistance.

5. General Physique.—The poor subjects are those of muscular strength, of obesity and of plethora, whereas the inactive and anemic subjects are quite the contrary.

6. Respiratory System.—Hewitt states that in lost consciousness all preëxisting defects are greatly increased, which certainly coincides with the experience of the writer during the past six years. Firm and closely fitting teeth may be a very great bar to easy anesthesia; such patients require a small mouth prop, as a rule, no matter whether ether or chloroform is used.

Subjects without teeth may suck their lips back and forth in a valve-like action which obstructs the air-way to a remarkable degree. Fixity of the lower jaw always makes the anesthesia difficult, whether the fixity is due to position or disease. Growths of the tongue, soft palate and tonsils may become turgescent and excite dyspnea. Decrease in the supply of oxygen usually adds to their size. Growths of the neck, thyroid gland, etc., usually obstruct respiration. All these conditions rather indicate the chloroform-ether mixture, or ether drop by drop.

Diseases of the larynx and trachea require chloroform or chloroform mixed with ether. Bronchorrhea, pulmonary, and pleural diseases, if active and progressive, indicate chloroform or chloroform-ether; if stationary, ether may be used cautiously. Recent pulmonary disease indicates chloroform or C. E.-ether sequence. The ether should be given most carefully and preferably drop by drop, so as to give exactly the required quantity and no more, with a bag cone, so as to warm the fumes as much as possible. When respiration and circulation are interfered with by such conditions as ascites and empyema, great care is necessary. The writer's opinion is that C. E.-ether or chloroform-ether is the best usually. Ether should always be at hand if chloroform is being used, so that if the evacuation of the fluid changes the condition of the circulation, it may be employed as a stimulant. In empyema if the lung itself is no longer diseased, ether alone may be used. In both ascites and empyema much danger will be avoided if the fluid is aspirated a few hours before the anesthetization.

7. Circulation.—Slight or compensated disease of the valves of the heart accepts ether well; cases which require cardiac sedatives will probably do better under chloroform or C. E. Cases which require stimulation will usually react better under ether alone than under chloroform in any way. When one is in doubt as to the exact condition of the heart, it is probably safer to use ether than chloroform. In the advanced cardiac cases, unless the patient must sit up to breathe, it is highly advisable to have him in the recumbent or semirecumbent posture, to give him plenty of air and to provide utmost freedom for the respiratory function. The cyanosis so often present with gas may overwork the right heart; therefore, the nitrous-oxide-ether sequence is not to be recommended. Orthopnea always demands ether and absolutely contraindicates chloroform.

Cases with intermitting pulse usually improve under ether and often under C. E., but commonly require stimulation after withdrawal of the anesthetic. Myocarditic and fatty hearts require great caution and had best receive straight ether drop by drop. Atheroma, if marked, usually indicates C. E., and especially if myocarditis is present. Recent previous cerebral hemorrhage renders ether dangerous. Aneurysm suggests C. E. with deliberation and caution, especially during the stage of struggling. The same dictum applies to venous thrombosis. Exhaustion and collapse require ether with care and precision. It is best to restore these patients by a moderate saline infusion before giving

any anesthetic. Intestinal obstruction demands a light degree of anesthetic because shock is present and great caution as to vomiting, of which there is much danger. It is commonly not accompanied by esophageal movements. The vomiting is usually more truly a regurgitation for which the anesthetist must constantly be on guard. Many recommend that a pillow be put under one shoulder, the mouth gag into place and the sponge forceps at hand; that the head be turned to the opposite side so as to permit the regurgitated fluid to collect in the lateral regions of the throat and mouth, wherefrom it may be wiped. The writer prefers Rose's position with the head extended over the edge of the table, so that the vomitus collects in the vault of the pharynx, whence it may be readily removed, while at the same time the respiratory current passes through the mouth held open by a gag while the tongue is pulled forward.

8. Central Nervous System.—Cases of fracture of the skull with symptoms of intracranial hemorrhage, if unconscious require no anesthetic, but if conscious, they had best receive chloroform, if the fracture is very recent, or C. E. or ether if less recent. In any case, the degree of anesthesia must be slight. Conditions of the brain, accompanied by semiconsciousness or unconsciousness, of which cysts, tumors, abscesses, and inflammation are the type, likewise require a light degree of anesthesia and usually do better under chloroform or C. E. If there are indications of depression, ether should be used. Nervous symptoms forming part of the symptom complex of chronic diseases, of which the various forms of nephritis are the best examples, usually require a light degree of anesthesia, and most of them do best with ether drop by drop.

9. Kidney Diseases.—Organic lesions probably have definite indications, functional lesions are usually unimportant. Unfortunately, medical opinion is widely divided as to the choice of anesthetic for these cases. Edebohls, who has done much kidney work, rarely uses chloroform for these cases. Weir states that probably ether is much the safer anesthetic for the reason that, whereas it may irritate the kidney, it does not damage it permanently, but that if the patient has a kidney susceptible to chloroform, he is practically certain to have serious symptoms as the result of the chloroformization. Hewitt, who is one of the most experienced living anesthetists, recommends that prolonged etherization should be avoided, and considers the C. E. mixture as the best. The writer has had opportunity to observe the results of ether and of chloroform alone and in mixture. On the whole, he inclines to the view rather strongly that brevity of operation, combined with etherization carefully carried out, drop by drop in a bag inhaler, is by all means the safest plan for these subjects. A very good rule is to infuse moderately with saline solution a large number of these kidney cases; this works well in stimulating the organs to do their work. Another procedure which the writer follows in private with great advantage, is to have the patients during the first six hours of convalescence from the anesthetic wrapped in several thicknesses of blanket next to the skin, thus constituting a veritable hot pack and relieving the kidneys of much of their work.

Diabetes is a condition which requires great care. Good judgment indicates that, when possible, the sugar should be reduced by diet before the operation is undertaken, and that brevity of operation should be observed as far as possible. Ether is undoubtedly best choice, but should be given most carefully. Other authorities, however, differ from this statement and prefer the C. E. combination. The tonicity of the chloroform is, however, of very great moment to these subjects in the writer's view.

Menstruation, pregnancy, and lactation are conditions which are quite unimportant with regard to anesthetics, with the sole exception that as a rule the pregnant woman should be anesthetized carefully so as to avoid struggling with its consequent dangers.

The foregoing are the chief elements of the subject, and the observations are the result of about six years' careful study in this field. It is hoped that their enunciation in this form will be helpful to those who are interested in making the question of anethesia a less worrysome one to the patients and more convenient to the operators.

CRYOSCOPY OF CEREBROSPINAL FLUID IN EPIDEMIC CEREBROSPINAL MENINGITIS.

By JOHN H. BAILEY, M.D.,

NEW YORK,

SENIOR PHYSICIAN BETH ISRAEL HOSPITAL HOUSE STAFF, N. Y.

THE molecular concentration of the cerebrospinal fluid in epidemic cerebrospinal meningitis is a subject that has been but little investigated, there being hardly more than a few casual references to it in the entire medical literature, as far as I could determine. It was with the hope that some information, at least interesting if not important, might be obtained that the present work was undertaken.

During the recent prevalence of epidemic cerebrospinal meningitis in this city, many cases were admitted to Gouverneur and Beth Israel Hospitals. Through the kindness of Dr. Francis Huber, who was then on service in these hospitals, ample material was obtained for my investigation.

The following brief remarks on the theoretical basis of cryoscopy may be serviceable. A pure fluid freezes at a higher temperature than the same fluid when holding solid substances in solution.[1] The freezing point of a solution under the same external conditions, such as atmospheric pressure, etc., depends (1) upon the solvent itself; this is of comparatively little importance; and, in the case of the body fluids, may be totally disregarded, since here we have to deal with the same solvent in all of the various fluids, namely water. (2) Upon the molecular concentration of the solution, [1], [3], [4], the greater the number of molecules held in solution, the greater the depression of the freezing point. The freezing point is not additionally influenced by the size or nature of the molecules, but is purely dependent upon their *number*;[3] *e. g.* a molecule of sodium chloride produces the same effect upon the freezing point as a molecule of dextrose, although these substances differ greatly in molecular weight and properties. When several substances are contained in solution in a fluid, the total freezing point of the fluid is equal to the sum of the freezing points which each substance in itself would produce [1], [6]. The ion exerts the same influence upon the freezing point as the whole molecule, [1], [3]. The less concentrated the solution, the more will the molecules be dissociated into their ions until, when a certain dilution is attained, the molecules are completely dissociated.

A normal solution of any substance as such (*i. e.* the number of grammes of that substance corresponding to its molecular weight dissolved in a liter of distilled water) causes a lowering of the freezing point equal to 1.88° C.

For the sake of convenience the following symbols are made use of: T stands for the total freezing point of the cerebrospinal fluid; S, for that part of the total freezing point due to the contained

sodium chloride; R, for that portion of T due to the remaining solid components of the fluid, *i. e.* T-S; $\frac{T}{NaCl}$, for the total freezing point divided by the NaCl number corresponding to the per cent. of sodium chloride found in the fluid; α, for the total number of molecules and ions in the fluid, represented in each case by 100; β, for the number of sodium chloride ions (since all the sodium chloride molecules are here dissociated); , for the number of molecules and ions of the rest of the solid constituents.

The freezing point was determined with Beckman's instrument; the sodium chloride estimated by the Salkowski-Volhard method; S obtained from the following formula , where P = the number corresponding to the per cent. of the substance contained in the fluid (in this case the per cent. of sodium chloride); P is multiplied by 10 in order to change the per cent. to grammes liter; M = the molecular weight of the substa : and -1.88 = the depression of the freezing point of a gramme molecule of dissolved solid per liter of distilled water. To illustrate: the freezing point of a 0.70 per cent. solution of NaCl *as such* equals $\frac{.70 \times 10 \times -1.88}{58.5}$ or -.225. This number, however, must be multiplied by 2, because in this dilution every sodium chloride molecule is dissociated into its two ions, and consequently we have twice as great a depression of the freezing point.

The effect upon T of the albumin content may be entirely ignored as is evident from the following: Sabanejew and Alexandrow, quoted by Hammerstein, give the molecular weight of albumin as approximately 14300. Let us say we have 2 per cent. of albumin in the fluid, an amount which is greatly in excess of that actually present. Now, a 2 per cent. solution of albumin would lower the freezing point only $\frac{2 \times 10 \times -1.88}{14300}$ or -.0026, a quantity so small that it may be totally disregarded.

Cellular elements and other solids held in *suspension* do not affect the freezing point; for, to produce a depression of the freezing point, it is necessary that the solid substances be in solution.

Altogether sixty-nine specimens of cerebrospinal fluid were examined; some of the cases being examined several times at varying intervals.

The following data and conclusions have been obtained from a study of my investigations:

Upper limit of T is -.815; lower limit, -.50; a variation of -.315. The vast majority of cases, however, 79 per cent., ranged from -.52 to -.64, a variation of only -.12. Average T is -.575, very close to the normal freezing point of blood. T oscillates much less than the freezing point of urine. The greater part of T is due to the sodium chloride content. T varies not only in specimens from different cases, but, also, in specimens from the same case at different times. T is not of any prognostic significance; some of the patients that recovered showed a high T, others a low T; while the same is true of several cases that terminated fatally.

The limits of S are -.352 and -.486, a variation of -.134; this may be considered a comparatively small variation. Most of the cases, 74 per cent., ranged from -.40 to -.45, a difference of only -.05. Average S is -.422. S is less inconstant than T.

The limits of R are -.062 and -.338, a variation of -.276. Most of the cases, 72 per cent., ranged from -.090 to -.180, a difference of -.09. Average R is -.152. Some of the fluids have a high T and a low S, others a low T and a high S, showing that in these cases the number of "feste" molecules, exclusive of those of sodium chloride, vary much.

The limits of the NaCl content are .55 per cent. and .76 per cent., a variation of .21 per cent. Most of the cases, .71 per cent., ranged from .60 per cent. to .68 per cent., a difference of .08 per cent., or reduced to terms of the freezing point, a difference corresponding to -.05, as is seen from the following $\frac{.08 \times 10 \times -1.88 \times 2}{58.5}$. Average sodium chloride content is .66 per cent. The amount of sodium chloride fluctuates less than T. This is due to (1) that molecule for molecule the sodium chloride varies less than the other "feste" molecules. (2) that, since every sodium chloride molecule is dissociated into its ions, for a difference of one molecule of sodium chloride there is twice as great a difference in the freezing point.

The quotient obtained by dividing the total freezing point by the number corresponding to the per cent. of sodium chloride is a quantity to which Korányi, who may justly be designated the father of clinical cryoscopy, attaches great importance in the examination of urine. In the cerebrospinal fluid of cerebrospinal meningitis $\frac{T}{NaCl}$ has for its limits .729 and 1.183, a variation of .454. Most of the cases, 74 per cent. ranged from .800 to 1,000, a difference of .20. Average $\frac{T}{NaCl}$ is .872.

Although this work has not been productive of any results that are available at present for positive practical purposes, the data obtained may be of scientific interest and value.

Sanitary Inspectors of Birmingham, Ala.—The Jefferson County, Ala., Medical Society, at its January meeting, acting as the county Board of Health, elected B. W. Walker chief sanitary inspector for the city of Birmingham for a term of two years commencing February 1, and J. B. Sparks assistant sanitary inspector for the same term.

FOREIGN BODY IN THE BRONCHUS; REMOVAL WITH THE AID OF THE BRONCHOSCOPE; RECOVERY.

By SIDNEY YANKAUER, M.D.,

NEW YORK.

On January 24, at 11.30 A. M., I was hastily called to see a child, 10 months old, who was said to be choking. Responding promptly, as the patient lived near my office, I found a well-nourished boy, coughing constantly, and the following history was given. The child had taken an orange-pit into its mouth. The mother attempted to remove it with the finger, when the child, beginning to cry, took a deep breath. The orange-pit disappeared and the child was immediately seized with coughing, dyspnea, and cyanosis. The child was taking deep and rapid breaths, it was somewhat cyanotic, and after each third or fourth respiration had an attack of spasmodic coughing. The pulse was 120.

Laryngoscopic examination was made with some difficulty on account of the small size of the throat; but it was possible to see the entrance of the larynx. The foreign body was not seen. Digital examination was also negative, and the fact that the child cried with a clear voice convinced me that the foreign body was not lodged in the larynx. The respiratory murmur was loud on both sides of the chest, and there were coarse sonorous râles over the whole chest. A diagnosis of foreign body in the trachea or bronchus was made, and Dr. Emil Mayer was called into consultation. He confirmed the diagnosis and advised immediate operation.

The child was then removed to a private hospital, and at 3.30 P. M. of the same day, four hours after the accident, it was operated on. Examination of the chest just before the operation showed that the right chest moved much less freely than the left. The normal respiratory murmur on the right side was absent, and was replaced by a faint inspiratory sibilant râle, loudest in the second half of inspiration. On the left side the breathing was exaggerated.

Chloroform was administered, primary anesthesia only being induced, and inferior tracheotomy was performed, with the assistance of Dr. Emil Mayer. A probe was readily introduced into the mouth through the tracheotomy wound and larynx, showing that the foreign body was not located there. The bronchoscope, 7 mm. external diameter, was then introduced into the tracheal wound and pushed forward until near the bifurcation. The foreign body could be plainly seen, lying with one end impacted in the right bronchus, the other against the opposite wall of the trachea. It was seized in the bronchoscopic forceps, but could not be withdrawn through the narrow lumen of the instrument, so that bronchoscope and foreign body were withdrawn together. The orange-pit measured 17 mm. long, 6 mm. wide, and 5 mm. thick. A tracheotomy tube was inserted.

On the following day the breathing had become normal in intensity on both sides, but there were many loud sonorous and moist râles over the whole chest. The temperature was 103.2°, pulse 130, respirations 30. On the second day the temperature was normal; the tracheotomy tube was removed, and the wound closed with adhesive-plaster strips. The recovery since then has been uninterrupted.

This case presents several points of interest. Attention is called to the importance of using a very small amount of chloroform, the anesthetic having been discontinued as soon as the trachea was opened. The case is one of the youngest thus far recorded. Inferior bronchoscopy was performed in preference to the direct method for the reason that it is impossible to introduce into the larynx a bronchoscope sufficiently large to permit the necessary manipulations, in so young an infant, without injuring the larynx. In some of the cases of direct bronchoscopy in infants that have been reported, secondary tracheotomy became necessary (Nehrkorn, *Deutsche medizinische Wochenschrift*, September 29, 1904). It is the first recorded case of successful removal of a foreign body by means of the bronchoscope in this city.

A SPINDLE-CELL SARCOMA OF THE BOWELS OPERATED ON SUCCESSFULLY

By J. B. BOUCHER, M.D.,

HARTFORD, CONN.

SURGEON TO ST. FRANCIS' HOSPITAL.

Mrs. R., age 38, born in Ireland, father died of tuberculosis, cause of mother's death unknown; she has four brothers and four sisters, living and well, and has had two children, living and in good health. The patient entered St. Francis' Hospital early in January, 1904, with the following history:

For the past year she had been losing some in weight, appetite poor, bowels constipated and irregular. At times she complained of considerable pain in the abdomen, particularly in the right inguinal region. The conjunctivæ were almost white, the skin was dry and rough, and the general expression was that indicating some morbid change going on in the system. Examination revealed a mass in the right inguinal region about four or five inches long, about one inch to the outer side of the appendix line, and attached to the crest of the ilium. The mass was only very slightly movable and seemed to be connected with the abdominal wall. It was slightly tender on pressure and felt like a solid tumor. The diagnosis of a probable malignant growth was made and an operation was advised and consented to.

An incision about four inches long was made over the mass, which was found adherent to the anterior abdominal wall and involving the cecum and several inches of ascending colon. The mass was dissected off the abdominal wall together with the parietal peritoneum and part of the muscle. It was then found that in addition to the involvement of the cecum and colon, the glands in the neighborhood were enlarged, some being as large as an ordinary marble. The appendix was grown into the solid mass, involving the cecum so there was only a small loop of the proximal end visible.

As the lumen of bowel was nearly occluded we decided to do a radical operation for the removal of the growth. We clamped off about six inches of small intestine, all of the ascending and about one-half of the transverse colon. We then removed all that portion between the clamps, going wide and including every gland that could be found. We then turned in the end of the transverse colon doing a double Lembert suture with silk, and made an anastomosis between the cut end of the small intestine and the side of the middle portion of the transverse colon, using silk sutures.

The abdomen was closed without drainage. The patient made an uninterrupted recovery with the exception of a small stitch abscess which discharged for a few days and closed. Her bowels moved freely without medicine on the third day. She left the hospital for her home at the end of five weeks. Microscopical examination of the specimen showed it to be a spindle-cell sarcoma.

On August 1 I received a letter from her family physician, Dr. John Mountain of Middletown, who had kindly referred the case to me. The doctor wrote: "The patient's condition remains very good. After returning home she had some diarrhea for a few weeks but gradually gained in strength and appearance. She has gained fifteen pounds in weight, and looks and feels very well. She does all her own work for the family and goes out washing two days a week. I have examined her and found no trouble in the abdomen."

Within the past week I have had an opportunity to examine the patient. Her condition is excellent. She looks and feels well. Examination of the abdomen reveals no trace of her former trouble and as it is now nearly one year since the operation, the result seems very encouraging.

From a search of the literature on this subject I am led to believe that this case of a patient living a year after removal of so extensive a sarcomatous growth of the intestines, and still in good health, must be a very rare one.

25 Chester Oak Avenue.

"Potato" Tumors of the Neck and Their Origin as Endotheliomata of the Carotid Body, with an Account of Three Cases.—Hastings Gilford and K. L. Hart Davis state that the occurrence of these growths in one particular region of the neck and in no other part of the body suggests that they must spring from some structure which is peculiar to this area. This particular growth is not an epithelioma, but an endothelioma. It is a tumor of the carotid "gland." Marchand first pointed out the exact origin of these growths. The writers report three cases of such growths which were noted in middle-aged or old men. The tumors were apparently of a high degree of malignancy, and rested upon the carotid arteries at the bifurcation. The position, relation to the carotid arteries, and penetration of the carotid sheath at the point of bifurcation all point to an origin from a structure situated in this neighborhood, and this structure is the carotid body. This body, as described by Marchand, is of the size and shape of a grain of rice, and is situated within the fork of the bifurcation of the two terminal branches of the common carotid. It reaches full development and permanent size in the sixth month of fetal life. Its anatomy somewhat resembles that of the hypophysis cerebri. It is glandular in nature, but has no ducts, and though it contains many nerves, it is not a ganglion. It is a mesoblastic structure, and its development is closely associated with that of the carotid artery. Between the vessels and nerves with which it is supplied there are masses of endothelial cells, of round or irregular shape, sometimes much like the acini of a gland. The function of this structure is unknown. The evidence seems fairly complete that the "potato tumors" are endotheliomata of the carotid body. As a rule, these tumors are looked upon as tuberculous, lymphomatous, or malignant glands. The best treatment is complete removal at the earliest possible date. It does not seem likely that this growth could be completely removed unless the vessel were taken away at the same time. This operation would be more likely to succeed if a temporary ligature were placed around the common carotid artery a week or so before the removal of the tumor, in order that a sufficient blood-supply to the brain would be ensured. The other alternative is the destruction of the growth by caustics. The former method, however, is preferable.—*The Practitioner.*

Scurvy Rickets, with Spontaneous Fracture of Three Long Bones.—Nathan Raw says that the term scurvy rickets is in reality a condition of scurvy, often, no doubt, superadded to rickets, but in its nature distinct. It is known as Barlow's Disease in Germany. Such cases are of great importance to hospitals and practitioners, for grave allegations of neglect and injury may be made, as in this case, on account of fractures, which may be found without any apparent cause. The patient whose history is given here was two years old, and had always been fretful and irritable, and had cried out when handled. It had been fed since birth on proprietary foods, and had never had any boiled or sterilized milk alone. The post-mortem appearances in this case were those of a typical case of severe rickets, with scurvy superimposed. Over the left parietal and occipital bones was an enormous swelling, which incision showed to be a large collection of pale fluid blood under the muscles. Three other swellings were found—one over the neck of the left humerus, one over the center of the left thigh, and one in the lower third of the right tibia. In each instance an extensive subperiosteal hemorrhage was found, with complete fracture of the bone. The cancellous tissue of the bones was very vascular and softened. The gums were soft, friable and very spongy. The stomach was almost completely digested. The general condition of these cases is one of profound anemia. Ecchymoses may appear. The temperature is variable. The cause of the disease is uncertain. It is doubtless due to some defect in the diet. The writer has all milk for the hospital children sterilized slowly. The milk is raised to a temperature of 200° F. and kept there for five minutes. He has never seen the slightest symptom of scurvy among these children. Artificial foods and condensed milk seem sometimes to produce scurvy. So does peptonized milk. There is liability in a case of scurvy to the formation of large swellings, which are often mistaken for abscesses. Treatment is satisfactory if taken fairly early. The fresh element omitted in the diet should be provided. A powdery steamed potato, beaten into a thin cream or milk, is excellent. Lemon or orange juice, in one-half teaspoonful doses, is useful three or four times a day. A little raw meat juice, and ordinary milk, if it can be digested, are of value. Dover's powder will relieve pain. The child should be protected from the weight of the bedclothes and should have complete rest. It should not be handled or bathed any more than is absolutely necessary. Scurvy rickets is not so common as it was ten years ago, which is doubtless due to more rational and intelligent feeding and a better knowledge as to its prevention.—*The Practitioner.*

Appendicitis in a Child Discovered by Rectal Examination.—Dan McKenzie emphasizes the fact that rectal examination should be undertaken as a matter of routine in all doubtful cases of illness in children, more especially in those in whom the symptoms point to the abdomen as the seat of disturbance. The writer reports a case in point. A boy aged 4 years was suffering from pyrexia and malaise when first seen. As he was subject to acute gastric attacks, nothing unusual was anticipated. On the day after the first examination, he complained of stomach-ache and pain on micturition. The abdomen seemed to be hard and tender. Per rectum, the bladder was felt to be full and fluctuating. As some cystic trouble was suspected, the patient was anesthetized and a catheter passed into the bladder, but nothing was found to account for the symptoms. Rectal examination cleared up the cause of the illness. Bimanual palpation of the pelvis and abdomen revealed an oval, rounded tumor about the size of a pigeon's egg, lying toward the right side of the pelvis, in the right iliac region. Appendicitis was diagnosed. At the operation, which was performed the same evening, it was found that the appendix was perforated in several places, and the organ was lying in a pool of pus, so that if surgical intervention had been delayed even for a day or two, the child would doubtless have died. Convalescence was complicated by the passage of a fairly large uric-acid calculus. After this, recovery was uneventful. The pelvis in a child is so much shallower than the pelvis in the adult that it is possible with a finger in the rectum to investigate the condition of the abdomen far more completely than can be done in later life. Anesthesia, in the writer's experience, is necessary for a satisfactory examination of this kind.—*The British Journal of Children's Diseases.*

WM. WOOD & CO., 51 FIFTH AVENUE.

New York, February 11, 1905.

THE NATURE OF VACCINE BODIES; PARASITIC OR DEGENERATIVE.

IN the November number of the *Journal of Medical Research,* Dr. James Ewing reviews the histology of vaccina and variola, and gives his reasons for believing the so-called vaccine bodies to be of degenerative rather than parasitic nature. He says that when such a study as Hückel's leads the investigator to a positive conclusion that the vaccine bodies are certainly cytoplasmic degeneration products, and practically identical data serve to convince other competent observers that the bodies are certainly parasites, it is obvious that the evidence fully justifies neither contention, and that a demonstration has not been reached. As the author's own study has not furnished any demonstrative proof of the nature of the vaccine bodies, it is, he says, hardly permitted to him to claim absolute certainty for his opinion that they are cytoplasmic degeneration products; but this view is very strongly favored by a great number of facts of which those chiefly concerned with his own study are the following: The specific vaccine body shows in many instances definite connections with the cytoplasm of the epithelial cell connections which are explicable only on the supposition that this body is a part of the cytoplasm. Moreover, there appear to be numerous transitional forms between the specific vaccine body and other homogeneous globules in the cells, which can be produced by diphtheria antitoxin. Again, the form, size, and structure of the vaccine body are so irregular as to suggest the cycle of a degenerative process rather than that of a living microorganism; and the criteria commonly required by zoologists for the identification of protozoa (*i. e.,* nucleus, spore-formation, multiplication) have not been demonstrated for the vaccine body. A study of vaccina shows that an active diffusible toxin, similar to that of diphtheria, is at work in the process from its beginning, but the production of such toxins is not the rule with protozoa. The comparative study of the action of vaccine on different animals shows that the same general process and in many respects the same peculiar intracellular changes are produced in widely different classes of animals, which suggests that the vaccine body is a particular form, assumed in some warm-blooded animals, of degenerating epithelial cells. There are, the writer says in summing up, possible sources of error in the foregoing conclusions, and he believes far more demonstrative evidence is needed before any real insight into the true nature of the vaccine body can be obtained.

Regarding the intranuclear bodies, again, the present data seem insufficient for positive opinion, pro or con, as to their protozoan nature. Certainly Councilman's intranuclear rings are very definite structures, exhibiting so much of the general appearances of protozoa as to establish at once a suspicion that such is really their nature. Ewing merely points out the difficulties which the average worker may encounter if he undertakes a critical study of these bodies. The behavior of the intranuclear bodies under different fixatives and stains is unsatisfactory for the protozoan hypothesis, the staining reactions of these bodies being identical with those of certain nuclear elements, viz., nucleoli and linin droplets. In pure variolous tracheal lesions fixed in formalin, all the intranuclear bodies present seem clearly identical with degenerating nuclear elements. After treatment with Zenker's fluid and Borrel's stain, there are found satisfactory transitional forms from homogeneous linin globules having no resemblance to protozoa, up to large vacuolated structures which belong in the cycle of the variola parasite. The intranuclear rings seem to occur only at a particular, not initial, stage of the necrosis of squamous epithelial cells. The intranuclear cycle is imperfectly represented in specific lesions of mucous membranes, and may be entirely missing in the cutaneous necrosis of rapidly fatal secondary hemorrhagic cases. On the other hand the full series of these bodies seems to occur only in variola, and only individual forms seem to be duplicated, and these imperfectly, in other lesions.

ARE THE DOCTORS OBSERVING?

A MEMBER of the New York State Legislature, who is known to his colleagues as "the Bowery Senator" (his patronymic is variously given as Sullivan and Fitzgerald), has introduced a bill designed to legalize the practice of "kinesipathy," as the new scheme for getting rid of disease by giving it the shake is called, and to secure for its "professors" the advantage of State recognition. By way of an elucidation of the term kinesipathy, the bill defines it as including "massage, therapeutic gymnastics, Swedish movements, mechanoneural therapy, somatopathy, seismotherapy, vibration, and vibrassage." It provides that thirty days after its passage "the New York Medico-Gymnastic and Massage Society, the Therapeutic Society for the Physical Education of Greater New York, and the Trepsis Association of Greater New York shall meet and select a board of three examiners in Kinesipathy. This board when confirmed by the State Board of Regents shall have the power to make rules and regulations for the practice of the kinesipathic art."

The *New York Times,* which is commendably orthodox in its medical views, has scented the danger to the community in the provisions of this bill, and makes some comments upon it in an editorial paragraph with the above title. "Examined and certificated," the writer truly says, "by a board chosen from among their own number, and confirmed by the State Board of Regents, this whole great company of men and women who yearn to treat the sick—and get their fees—without taking the trouble to become doctors would be safe from the occasional prosecution which they are pleased to call persecution, and they would attain to a professional dignity that would be of enormous benefit to their business." The note concludes with an expression of wonder, "how soon the medical societies are going to get active."

The *Times* writer should make the acquaintance of the members of the Committee on Legislation of the State Medical Society before asking such a foolish question. "Are the doctors observing," indeed! The kinesipathy bill was introduced on February 2 in the Senate Chamber of the Capitol, but on the day preceding this, as reported in the MEDICAL RECORD of last week, in the Common Council Chamber of the City Hall at Albany a resolution was adopted unanimously and enthusiastically by the delegates of the Medical Society of the State of New York, then in annual session, denouncing this very bill—conceived in iniquity, but not yet born—and all other pernicious medical bills of like nature. The Society, informed of the intended introduction of the bill, called upon the Legislature to refuse to sanction it or any other efforts of incompetent and ignorant persons to secure the privilege of preying upon the community by the practice of special and peculiar methods of treatment.

If the denunciation of a bill before its introduction is not an evidence of activity sufficiently intense to satisfy the most anxious friend of legitimate medicine, we don't know what is. The doctors are observing—at least those of them who constitute the Committee on Legislation of the State Society—and the other doctors and citizens in general . . the State of New York owe them a debt of gratitude for their watchfulness.

"PLACE AUX DAMES."

OUR esteemed contemporary, the *Medical News,* has deserved well of posterity by directing attention to the observation that, in addition to the well-known risk of superficial burns, the vocation of the radiographer exposes him to the more insidious danger of damage to the spermatogenetic function. *Vetat pudor,* but a sense of justice to thousands yet unborn impels us to disclose the fact that, according to the revelations of a recent investigator, woman has still greater cause to fear this fell destroyer of germ cells than her tougher congener. Even the sheltered seclusion of the ovary affords no protection to its precious freight against the baleful emanations fathered by the German physicist. Halberstaedter, in the *Berliner klinische Wochenschrift* of January 16, describes experiments on rabbits which lead him to conclude that the function of the ovary is even more susceptible to the deleterious effect of the Röntgen ray than is that of its male analogue. So real does the danger seem to this author, that he recommends that prophylactic measures be carried out to guard against injury to the nurses in attendance in *x*-ray laboratories, by the use of suitable protective appliances, and that in treating abdominal conditions in women by the rays, the risk to the ovaries should always be kept in mind. Three sets of female rabbits were used in the experiments. The first series was rayed for half an hour on two occasions several days apart, while the second set was exposed twice as often. In each instance the animals were placed on the back during the treatment, with the right half of the abdomen protected by a plate of lead. At the autopsy about two weeks later, in every instance it was found that the left ovary was much smaller than the right, usually only half as large, and was devoid of Graafian follicles. A third series of tests was made in which the condition of the ovaries before treatment was established by laparotomy and inspection, so that accidental variation between the two sides could be excluded. Microscopical examination of the organs showed that ten days after the treatment the number of Graafian follicles was greatly reduced, while at the expiration of fifteen days they had all disappeared. In the animals of the first series primordial follicles and primitive ova were still distinguishable, so that a return to function was possible, but in the ovaries of the second series, destruction was so complete, that it seemed more than doubtful that new Graafian follicles could ever be produced. No doubt, when the results of Halberstaedter's experiments become known, the disciples of Malthus, whose advertisements appear so prominently in the newspapers, will find the installation of *x*-ray apparatus a profitable addition to the equipment of their "sanatoria."

LUCID BREVITY.

IN his inaugural address the new President of the Academy of Medicine used the words "lucid brevity" as describing the characteristics he particularly wished to see in the communications laid before that body. "Never," writes an ex-President of the Academy in a note to the MEDICAL RECORD, "were two words more aptly put together. Would that they might be woven into the web of all medical discourse, and water-marked on every page of medical writing! Verbosity," he continues, "is the plague of scientific discussion. It may arise from inability to think clearly, but quite as often it results from inability of the speaker or writer to lose himself in his subject. Certain tricks of verbiage find their usefulness in making and keeping the author's personality as vivid to the listener or to the reader as it is to himself. As one of these tricks may be mentioned the over-frequent use of the first person singular. In a reprint containing twelve small pages now before me, this use of the pronoun occurs 56 times. It is needless to say that that article is not an example of 'lucid brevity.' Let us hope that Dr. Dana, as presiding officer, will have the hardihood to make such use of the gavel, in extreme cases, as will secure a measure of brevity whether 'lucid' or not. If he does this, he will add greatly to the interest of the proceedings."

CHRISTIAN SCIENCE DUPES MUST PAY THEIR OWN DAMAGES.

THE Supreme Court of New Hampshire has recently decided that persons who knowingly submit themselves to treatment by Christian Science "healers," must not expect to recover money damages for any injurious consequences that may arise. The case was one in which a healer tried to dismiss the thought of a recurrent attack of appendicitis. The patient was a woman who had had an attack from which she recovered under medical treatment. When a recurrence took place she hired a "scientist" to disperse the claim by sitting in front of her and making assertions while she read Mother Eddy's book. As she grew steadily worse she finally became alarmed, called in her physician, was operated upon, and recovered. She then tried to recover damages from the healer who didn't heal, but the judge said the dupe was just as guilty as the duper, and that if it was illegal for the defendant to treat the plaintiff as he did, it was equally illegal for her either knowingly to employ him to give her such treatment or to consent to be so treated. One might say this was a good ruling, for the plaintiff was a fool, and it served her right nearly to pay with her life for her folly. But, on the other hand, the law ought to protect weaklings and fools from the machinations of crafty knaves, and when Christian Scientists know there will be nothing to pay if their victims die, society will have lost a powerful defense against

the onslaughts of the readers and healers of the Church of Eddy.

The Value of Filtration of the Public Water Supply.

According to a statistical study made by the Chief of the Bureau of Filtration of the City of Philadelphia the average number of cases of typhoid fever for each week from the beginning of the year to February 3 was 84 among a total population estimated at 1,300,000. Of this number only one occurred in the West Philadelphia district, with a population of 46,805, furnished with filtered water; while there were six cases in the remainder of West Philadelphia, having a population of 101,566, not yet supplied with filtered water. In the Twenty-first and Twenty-second wards, with a population of 113,755, furnished with filtered water, there was not a single case of typhoid fever for the week ending February 3, and only one case for each of the four preceding weeks of January. The number of cases of typhoid fever per 100,000 for the whole city decreased from 7.65 in the week ending January 6 to 5.87 in the week ending February 3.

News of the Week.

Examination of the Eyes and Ears of Pupils in Public Schools of Vermont.—The following is the text of an act recently passed by the General Assembly of the State of Vermont: "The State Board of Health and the Superintendent of Education shall prepare or cause to be prepared suitable test cards, blanks, record books, and other needful appliances to be used in testing the sight and hearing of pupils in public schools and necessary instructions for their use; and the superintendent of education shall furnish the same, free of expense, to every school in the State. The superintendent, principal, or teacher, in every school, during the months of September in each year, shall test the sight and hearing of all pupils under his charge and keep a record of such examinations according to the instructions furnished; and shall notify in writing the parent or guardian of every pupil who shall be found to have any defect of vision or hearing, or disease of eyes or ears, with a brief statement of such defect or disease; and shall make written report of all such examinations to the superintendent of education as he may require."

Sanitation in the Canal Zone.—From communications received at Washington from Gov. Geo. W. Davis and from Mr. John Barrett, United States Minister at Panama, it appears that the reports concerning health conditions in the Canal Zone have been grossly exaggerated. There is no probability of an outbreak of yellow fever, for the few cases recently reported are said to be sporadic and the very active measures being carried out under the direction of Col. W. C. Gorgas are expected to stamp it out entirely. Of the eighteen cases that had been reported up to January 20, 1905, since July 1, 1904, when the United States authorities took charge of the sanitation, only three had a fatal termination, and only one of the deaths occurred within the last three and one-half months. In the families of the Americans employed on the Isthmus, there have been three cases of yellow fever and only one death. Of the employees hired on the Isthmus, five have been stricken, but only one has succumbed to the disease. The total number of cases of Americans not employed on the Isthmus, including those of the cruiser *Boston*, where the disease broke out, three weeks ago, have been nine cases and five deaths. Two cases of smallpox have been reported since the American occupation, but these were imported. There is no typhoid fever or plague, and of the 4,000 employees only three per cent. are on the sick list for any cause.

The Nathan Lewis Hatfield Prize for Original Research in Medicine.—Five hundred dollars will be awarded by the College of Physicians of Philadelphia to the author of the best essay submitted in competition on or before March 1, 1906, subject, "The Clinical and Pathological Diagnosis of Sarcoma." Essays must be typewritten, designated by a motto or device, and accompanied by a sealed envelope bearing the same motto or device, and containing the name and address of the author. They must embody original observations and researches. The Committee reserves the right to make no award if none of the essays submitted is considered worthy of the prize. Further information may be obtained by addressing Dr. Francis R. Packard, College of Physicians, 219 South 13th street, Philadelphia, Pa.

Health Department Changes.—The Division of Bacteriology of the Department of Health has been abolished, and two new divisions have been created. One will be known as the Division of Laboratories, and the other as the Division of Communicable Diseases. The former includes the Research, Chemical, and Vaccine Laboratories, under the immediate charge of Dr. Wm. H. Park, James P. Atkinson, Ph.D., and Dr. J. H. Huddleston respectively; the whole division being under the direction of Dr. Hermann M. Biggs, Medical Officer. This division will superintend the preparation of vaccine virus, diphtheria and tetanus antitoxin, tuberculin, etc., and conduct all experimental bacteriological work, the examinations of milk, food, etc. The Division of Communicable Diseases will have sanitary supervision over tuberculosis, pneumonia, typhoid fever, malaria, cerebrospinal meningitis, puerperal septicemia and abortion; also it will have charge over the administration of antitoxin in diphtheria. The examination of diphtheria cultures, samples of sputum, blood, etc., will continue to be a part of the work of this division, and it will be in charge of Dr. J. S. Billings, Jr., who has been the Assistant Director of the Division of Bacteriology. Dr. Thomas L. Fogarty has been appointed Assistant Sanitary Superintendent for the Borough of Brooklyn. He is 38 years of age, a graduate of the Long Island Hospital Medical College in 1891, and for the last ten years has been connected with the Department of Health in various positions.

For a Pure Milk Supply.—The Philadelphia Milk Exchange recommends all engaged in the production and distribution of milk that no milk be purchased or sold that does not conform with the following conditions: The cows shall be healthy and free from all disease; milk from any cow suspected of illness shall be discarded from the herd milk; the dairyman and his household must be free from all contagious disease; milk pails should have covered tops, with a small opening protected by wire sieve and cloth strainer; all cans and dairy utensils should be perfectly clean before being used; no milk should be kept in or sold from living rooms or any room connected with the stable; bottles and bottling apparatus should be scrupulously clean, as well as the room for filling bottles, the boxes for storing bottles or cans, and delivery wagons, inside and outside. In addition Dr. A. C. Abbott, president of the Board of Health, has recommended that all milk cans should be thoroughly washed before being returned to the farms or dairies whence they came, and that dairymen and milk dealers generally should effect-

ively screen all rooms in which milk is handled so as to exclude flies, which are known to be an important medium for the transmission of infectious diseases.

Dr. L. Duncan Bulkley will give a special course of four lectures on "The Relation of Diseases of the Skin to Internal Disorders," in the Out-patient Hall of the New York Skin and Cancer Hospital, Second avenue, cor. Nineteenth street, on Wednesday afternoons, at 4:15 o'clock, commencing March 1, 1905. The course will be free to the medical profession.

Legislative Action Sought Against a Blacklist.—The physicians of Millbury, Mass., have entered into a mutual agreement that they will not attend professionally, except in case of emergency, any person who wilfully refuses to pay for medical services rendered previously by any other physician of the place. Some time ago the physicians of Monroe County, N. C., entered into a similar agreement. All who had refused to pay doctors' bills were put on a blacklist, and an agreement was entered into not to visit any of them until the account was settled. The doctors stuck to their agreement regardless of the consequences, and the Legislature has been called on by the deadbeats for relief. A bill has accordingly been introduced compelling a physician to attend the sick when money is tendered for his services, if the physician has no other reason for refusing to answer the call than the blacklist agreement.

Government Care of Lepers.—Two bills concerning lepers are now under consideration by the House Committee on Interstate and Foreign Commerce. One bill provides for the establishment of a sanatorium for the care of the 275 persons who are said to be lepers in this country, the institution to be located in the arid region of the Northwest. The other bill is one appropriating $150,000 for the scientific study of the disease in Hawaii.

Sing Sing Prison Declared to Be Insanitary.—A report recently submitted to the Legislature by State Engineer and Surveyor Van Alstyne and Superintendent of Prisons Collins declares that Sing Sing Prison is "a hotbed for the culture and spread of tuberculosis," and recommends that it be abandoned as "unfit for human habitation," and that a new prison be erected on the west side of the Hudson River at a point in Rockland County, nearly opposite the site of the present institution, not far from Haverstraw.

Pure-Food Bill in Pennsylvania.—A bill has been introduced into the Legislature of the State of Pennsylvania making it a misdemeanor to manufacture, sell, consign, offer for sale or have in possession with intent to sell, any article of food or drink which contains formaldehyde, sulphurous acid or sulphites, boric acid or borates, salicylic acid or salicylates, saccharin, dulcin, glucin, betanapthol, abrastol, asaprol, fluorides, fluorborates, fluorscilicates or other fluorine compounds, and all other preservatives injurious to health. The bill does not prohibit the use of common salt, saltpeter, wood smoke, vinegar and the condimental preservatives, such as turmeric, mustard, pepper and other spices. The penalty for violation of the act is a fine of not less than $60 nor more than $100, with costs, or imprisonment not exceeding sixty days, or both.

Cincinnati Society of Medical Research.—At the last regular meeting of the Society in the Cincinnati Hospital Laboratory, the following officers were elected for the year: *President,* Dr. Samuel Iglauer; *Vice-president,* Dr. H. J. Whitacre; *Secretary* and *Treasurer,* Dr. H. J. Schroeder; *Executive Committee,* Drs. Carl Hiller and S. P. Kramer. Papers were read by Dr. M. L. Heidingsfeld, on "Myoma Cutis," and by Dr. Iglauer on "An Attempt to Relieve Atrophic Rhinitis by a New Operation."

The Fox River Medical Society, at its annual meeting, held at Green Bay, Wis., January 17, elected the following officers: *President,* Dr. A. C. Mailer, of De Pere; *First Vice-president,* Edward Sawbridge, of Stephenson, Mich.; *Second Vice-president,* W. A. Gordon, of Oshkosh; *Secretary* and *Treasurer,* J. S. Reeves, of Appleton, Wis. The next annual meeting will be held at Green Bay.

Orleans Parish Medical Society.—At the installation meeting of this Society, held January 12, the following officers for 1905 were installed: *President,* Dr. L. G. LeBeuf; *First Vice-President,* Dr. J. A. Storck; *Second Vice-President,* Dr. John F. Oechsner; *Third Vice-President,* Dr. S. M. D. Clark; *Secretary,* Dr. Allen Eustis; *Treasurer,* Dr. Jules Lazard; *Librarian,* Dr. Homer Dupuy; *Additional Members Board of Directors,* Drs. M. J. Magruder, Gordon King, and J. G. Dempsey.

Memorial Bust of Dr. Christian Fenger.—Very soon there will be formally presented to the Chicago Medical Society by its members a memorial bust of the late Dr. Christian Fenger. This bust will be placed in the Cook County Hospital, on the surgical staff of which institution he served for twenty years. As considerable money will be left after paying for the bust, it is thought that this will be used to establish a Christian Fenger fellowship in one of the local colleges.

Annual Meeting of Illinois State Board of Health.—At the annual meeting of this Board, recently held, Dr. George W. Webster of Chicago was re-elected President of the Board; Dr. James A. Egan of Springfield, Secretary, and Dr. P. S. Wessel of Moline Treasurer. The Board has given its endorsement to a bill recently introduced in the Legislature which provides for the establishment of a State Hospital for Consumptives.

Another X-Ray Casualty.—Mrs. Elizabeth Fleischmann Aschheim, a member of the Röntgen Ray Society, well known on the Pacific coast for her skill, has been obliged to have the right arm amputated on account of *x*-ray burns. The effect of the rays first appeared in the hand about a year ago, but Mrs. Aschheim did not give up work until six weeks ago.

Diphtheria on Staten Island. — Forty-four cases of diphtheria have been reported to the Health Department during the last two weeks from the village of Elm Park in Richmond borough, and the S. R. Smith Infirmary at New Brighton is crowded with patients. The local public school has been closed, and an unusually large corps of Health Department physicians is at work in the infected section.

Typhoid Fever in Winnipeg.—More than 250 cases of typhoid fever have developed in Winnipeg in the last seven weeks, and the percentage of deaths has been alarmingly high. The health officers and city physicians are unable to learn the cause of the epidemic. The drinking water of the city is taken from an artesian well, and has been pronounced by experts to be pure. It is said that the mayor of the city has requested the Health Board of New York to send a sanitary expert to determine the source of the infection.

The Osteopaths and Their Bill.—This is evidently going to be a great year for registration bills. The medical shakers and the spectacle men are clamoring for a Regent's license, and the osteopaths have renewed their appeal for the seventh or eighth time. The new bill, to be introduced by a Buffalo senator, will provide that there shall be a Board of Osteo-

pathic Examiners, consisting of five persons, selected by the Regents from ten nominees named by the New York Osteopathic Society. Those who pass the examinations are to be licensed, and have the privilege of attaching the initials "D. O.," meaning Doctor of Osteopathy, to their names.

Graft in the Health Department.—Health Commissioner Darlington has asked the Municipal Civil Service Commission to create the position of inspector of supplies to prevent the alleged wholesale looting of department property going on in the city hospitals and other branches of the department.

New Hanover County, N. C., Medical Society.—At a meeting of this society held January 26, the newly elected officers were installed as follows: *President,* Dr. W. D. McMillan; *Vice-President,* Dr. D. W. Bullock; *Secretary* and *Treasurer,* Dr. S. E. Koonce; *Hospital Visiting Committee,* Drs. A. H. Harris, S. E. Koonce, D. W. Bullock, and Pride Jones Thomas.

Hospital News.—*Milwaukee County Hospital.*—The Milwaukee County, Wis., Medical Society has prepared a bill for the legislature, removing the management of the Milwaukee county hospital from the county board and placing it in the hands of a board of trustees.

Bill Concerning the Medical Staff of Cook County Hospital.—Senator Carl Mueller, of Chicago, has introduced a bill in the Senate of Illinois providing that physicians and surgeons of Cook County shall be apportioned among the recognized schools of medicine in such proportions as the Board may from time to time determine, the physicians and surgeons appointed to hold their positions for a term of six years, and internes eighteen months. The various schools are now given representation, but the bill is intended to legalize the practice.

New York State Tuberculosis Hospital. — The first report of the State Hospital for Tuberculosis, at Raybrook, in the Adirondacks, was presented to the New York State Medical Society by the Superintendent, Dr. John H. Prior. Of the eighty-two patients admitted, eleven have been discharged as cured. Of the remainder five have not been in the hospital long enough to justify any conclusions, nineteen have apparently recovered; the disease of thirty-four has been arrested, and all the rest show improvement. "The law creating this institution, and under which it has been in operation for a period of six months," says Superintendent Prior, "seems to be eminently satisfactory. It contains many new features which have never before been tested. The requirements for admission and the methods designed to limit treatment to incipient cases only will be adopted and tried by several other states in the near future. Thus far it seems unnecessary to advise any changes in the organic law."

The Late Dr. Manley.—At a stated meeting of the New York County Medico-Pharmaceutical League, held at the Hotel Astor on January 24, 1905, the following resolutions were offered: *Whereas,*—In the demise of our late Ex-President, Thomas H. Manley, M.D., the medical profession has lost an honored and worthy member, who for many years contributed to medical science and surgical skill; and *Whereas,*—We realize that he might have given to this society the benefit of many years of valuable advice and unselfish personal service, it is with profound regret that we bow to the inscrutable will of Divine Providence; and therefore be it *Resolved,* That in the loss of Thomas H. Manley, M.D., there has been taken from our midst a courteous gentleman, a benevolent and most useful citizen; and be it further *Resolved,* That these resolutions be spread on the records of this society; and that they be published in the medical press, and a copy thereof be transmitted to the family of the deceased. L. W. Zwisohn, M.D., Herman J. Boldt, M.D., Samuel F. Brothers, M.D., Committee.

The Medical Board of the Harlem Hospital adopted the following: *Resolved,* that by the death of Dr. Manley we have lost a highly esteemed and eminently proficient member of the Attending Staff. By his work at the Hospital and his highly appreciated literary abilities he has made his name known to the Profession. *Resolved,* that a copy of these resolutions be sent to the family of Dr. Manley, that it be published in the Medical Press, and that these words be entered upon our minutes. Theodore Keune, M.D., W. H. Luckett, M.D., Committee.

Obituary Notes.—Dr. Homer L. Bartlett of Brooklyn, N. Y., died at Thomasville, Ga., on February 3, at the age of seventy-four years. He was born in Jericho, Chittenden Co., Vt., and was graduated at the College of Physicians and Surgeons in this city in 1856. He practised in Brooklyn for a year and then was obliged to return to Vermont for his health. Upon his return he opened an office in Flatbush in 1857, and from that time was most active in all public affairs. He organized the Flatbush Health Board and became Health Commissioner. Later he organized the Flatbush Police Department and was chosen as President of the board. For many years he was visiting physician to the Kings County Penitentiary. He was also Vice-president of the Kings County Medical Society, a member of the State Charities Aid Association and of the American Medical Association.

Dr. Charles C. Ellis of Somerville, Mass., died of pneumonia on January 28, at the age of fifty-seven years. He was born at Berlin, Vt., was graduated from the Medical Department of the University of Vermont in 1867, and for many years practised medicine in Manchester and Nashua, N. H. He removed to Somerville about fifteen years ago.

Dr. Otis Eugene Hunt died at his home in Newtonville, Mass., on January 20, at the age of eighty-two years. He was born in Sudbury and was graduated from the Berkshire Medical College in 1848. He retired from active practice in 1883.

Dr. Daniel O. Polin of Springfield, Ky., died on January 14. He was born near Harrodsburg, May 28, 1829, and was graduated from the St. Louis Medical College in the class of 1851. He was president of the Washington County, Ky., Medical Association and the oldest practising physician in that part of the State.

Dr. T. M. Ward of Canton, Miss., died on January 18, at an advanced age. He was born in Maryland.

Dr. G. W. Harrison of Ashland, Wis., died January 12, at Grand Rapids, Mich. He was a graduate of the Rush Medical College, Chicago, in 1881.

Dr. W. R. Read of Boston died suddenly on February 1, at the age of seventy years. He was born in Scotland and was graduated in medicine from the University of Pennsylvania. He retired from active practice about twenty years ago.

Dr. Calohill M. Stigleman of Floyd, Va., died on January 30, at the age of seventy-five years. He was a graduate of the Medical College of Virginia in the class of 1857, and served in the medical department of the Confederate Army during the Civil War.

Dr. J. P. Haynes of Beaumont, Tex., died on January 26, at the age of seventy-eight years. He was a graduate of the Medical Department of Tulane

University in the class of 1870. He retired from active practice some years ago.

Dr. HUGH B. MCCONNELL of Somerville, Mass., died on January 25, as the result of an operation. He was born in Toronto thirty-four years ago and was graduated in medicine from Trinity College, Toronto, in the class of 1891.

Dr. MICHAEL O'HARA died at Philadelphia on January 31 at the age of seventy-two years. He was graduated from the medical department of the University of Pennsylvania in the class of 1852. At the outbreak of the Civil War he enlisted in the Navy as an assistant surgeon, and he afterwards became surgeon to the 150th Pennsylvania Volunteers.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

[illegible]

LONDON, January 20, 1905.

IT is not always easy to obtain a late history of operation cases, but there was an interesting exhibit at the Clinical Society's meeting on Friday. Mr. Jonathan Hutchinson, Jr., showed the case on which he performed intracranial resection of the second division of the fifth nerve, two years ago. Complete relief to the symptoms has continued up to this time, and he suffers no inconvenience from the anesthesia.

Dr. Robert Jones read a paper at the Medical Society on the 9th inst., in which he discussed the relation of functional insanity to neuroses. He regarded insanity as the negation of sanity, thus including every form of mental abnormality. As there is no standard of health there is none of sanity. The final criterion is conduct. Dr. Jones mentioned cases of temporary delirium in febrile states sent to asylums with a diagnosis of insanity.

The most convenient test, he said, was the presence of illusions, delusions, hallucinations influencing conduct. As a rule, these were functional, but in time might be related to organic changes. The most highly evolved senses—sight and hearing—contributed more to these delusions than the more stable but less informing smell and taste. Tactile sensations were associated with hysteria; visual and auditory with insanity. Hysteria might, in fact, be regarded as a "lower grade insanity." Cases of loss of memory and of double consciousness often recovered quite suddenly, and other conditions, such as hypochondriasis, chorea, neurasthenia, epilepsy, etc., leaving no structural alterations, must be put down as functional. Early treatment was insisted on, as minute variations continued over long periods might make it possible for disorder of function to lead to organic ch[illegible]

Dr. Mercier thought the paper supported his view, that all insanity was functional. Every twenty-four hours the mind normally ceased to functionate for a time in sleep. In insanity periods of cessation of function occurred, but at irregular intervals. Cells might be damaged, but it was those parts of them which were not damaged that produced symptoms.

Dr. T. B. Hyslop commented on the difficulty of distinguishing some cases of neurasthenia from general paralysis of the insane. He held the important point to be, not the illusions or delusions, but the lesion to which they were due and which prevented the patient from perceiving that they were only illusions.

Dr. Andriezen did not admit that functional insanity existed, nor could he think that functional disorder could [illegible]me organic disease. He said that in cases of epilepsy diagnosed as functional he had found areas of cortical sclerosis. He did not think the post-epileptic alteration of personality was functional. As to periodic attacks of melancholia, or to those which occurred in dipsomania, he thought they were due to some maldevelopment or malnutrition, causing the cerebral mechanism to act in a faulty manner.

Dr. Batten read a paper on encephalitis and its relation to acute anterior poliomyelitis, in which he described some acute intracranial symptoms as occurring in children in the summer season, [illegible] paralysis, which cleared up rapidly but not completely. He met with twenty-nine cases of anterior poliomyelitis and eight of polioencephalitis in the summer of 1904. More pathological evidence was wanted and he hoped on a future occasion to produce it. He grouped his cases according to the part affected, thus: (1) Those in which the cerebral hemispheres were affected; (2) those in which the cerebellum, and (3) those in which the cranial nuclei were affected.

Dr. Beevor said the view long entertained of these cases of sudden paralysis in children was that they were due to thrombosis of the larger veins, but that was hardly a sufficient explanation. There was considerable evidence that the cause was more probably thrombosis of the smaller vessels.

Dr. David Lawson demonstrated to the Medico-Chi. on the 10th inst., some changes which take place in the lungs and the pleura, chiefly in pulmonary tuberculosis, as shown by skiagraphs. He began by showing the difference in the behavior of serous fluid alone and of the same fluid *plus* air in a rubber bag. In the former the upper surface of the fluid was ill-defined and concave; in the latter sharply defined and horizontal. The same difference was shown between serous effusions and hydro- or pyo-pneumothorax. Skiagrams were thrown on the screen from a case of pyopneumothorax, taken four hours before operation, three months after it, and nine months later, the lung being then fully expanded. Other skiagrams showed the appearances in serous effusion before and after operation, when there had been compensatory emphysema, and again when there was consolidation and with cavities, were also shown, as well as lapsed lung, thickened pleura, dry pleurisy, tuberculosis with consolidation and with cavities, were also shown, as well as a case in which four cavities were located during life and the diagnosis confirmed by photograph of the lung after death.

In the discussion considerable differences of opinion were expressed as to the value of the *x*-rays for diagnosis, several fellows considering that ordinary physical signs could detect disease quite as early. Dr. Walsham was confident that pus was more opaque than serum, though some observers doubt this. The position of the heart was of less value in children than in adults. He had never seen a shadow in dry pleurisy.

Dr. K. Fowler said in cases of tuberculosis the shadow might extend beyond the bounds of the auscutatory sounds. There was need for great care in interpreting skiagrams. His experience was rather disappointing. In aneurysm the rays were of more use than in other conditions.

Dr. Thos. Woods, who died in his 90th year, attained no little success outside his profession, as well as in. Though in general practice he pursued philosophical and scientific studies, and contributed to their advance. He wrote "Reasons Against the Theory of Evolution," and the account of "Lord Ross's Telescope," as well as important papers on Thermochemistry, besides contributions to strictly medical subjects. All the time he was a busy man, with a large practice. He was M.D., Glasgow; L.R.C.S.I., M.R.C.S.E.

OUR LETTER FROM THE PHILIPPINES.

(From Our Special Correspondent.)

[illegible] OF THE [illegible] SMALLPOX COMMISSION—MONKEYS IMMUNE AGAINST SMALLPOX, THOUGH SUSCEPTIBLE TO VACCINA—[illegible] OF PLAGUE IN HONG KONG—POOR PHYSIQUE OF THE FILIPINO—INADEQUATE MEDICAL ATTENDANCE IN THE PROVINCES.

MANILA, P. I. DEC. 15, 1904.

AT the December meeting of the Manila Society the principal matter of interest presented was a paper by W. R. Brinckerhoff, M.D., and E. E. Tyzzer, M.D., entitled "Vaccinia and Variola." It will be remembered that these two medical men belong to what is ordinarily known as the Harvard Smallpox Commission. They came from Boston to Manila for the purpose of continuing the work which had been commenced at the former city about two years ago during the smallpox epidemic which was present at Boston at that time. Dr. Brinckerhoff explained that the commission was organized with the view of attacking the smallpox problem at different points simultaneously by a number of different workers.

Owing to the continual presence of smallpox in the Philippines and the facilities with which monkeys for experimental purposes could be obtained, it was decided that it would be desirable for at least two of the workers to come to Manila. The question of expense, however, was a serious drawback, but at that juncture Dean C. Worcester, the secretary of the interior for the Philippine Islands, happened to be in Boston, and, upon learning of this plan, kindly agreed to lend his assistance. The Insular Government thereupon aided the scheme, with the result that Drs. Brinckerhoff and Tyzzer came to Manila. They began work here last April, which has been uninterruptedly pursued up to the present time. A large amount of material was collected, much of which has been examined, but the greater portion of it is to be taken to the United States, where it is expected that it can be worked up to better advantage. Bacteriologically much the same results were

obtained with vaccination and smallpox lesions as in the United States. The work was seriously interfered with by the non-susceptibility of the Philippine monkey to smallpox. Every conceivable method was tried for the purpose of infecting these animals with the disease, but in only one instance was a typical lesion produced. It was not possible to cause an eruption in the ordinary sense of the term. In the one monkey that was successfully inoculated only a very few skin lesions were found. The authors are of the opinion that, while monkeys are more or less susceptible to vaccination, their susceptibility to smallpox is very limited. A number of instances were cited by the authors in which monkeys had been exposed to the disease under natural conditions and had not contracted it. This observation was further supplemented by one of the speakers who took part in the discussion, who stated that on the transport *Liscum*, which was detained last May at the Mariveles Quarantine Station, on account of smallpox, there were 159 persons aboard the vessel. Of this number 154 had been previously vaccinated. The remaining five all contracted the disease. With the steerage passengers, among whom the smallpox broke out, there were two monkeys, which were almost constantly in close contact with the persons in whom the disease appeared, yet they did not contract it. If monkeys were susceptible to smallpox to any extent it would certainly seem that an infection that could find the five unprotected persons among 159 would also have found them. From the foregoing résumé it will be seen that it was not possible to make much advance because there were no animals upon which satisfactory experiments could be made. It is now proposed to continue the experiments with orang-outangs, because the preliminary work has shown that they seem to be more susceptible to smallpox and the microscopical findings resemble very closely those found in human beings.

There was one case of plague reported in Singapore last week. Hong Kong, which has enjoyed an entire freedom from the disease for a number of weeks, is again infected. Three cases and three deaths were reported during the past two weeks.

A physical examination of Filipinos, recently made, shows in an unmistakable manner what poor physicians prevail among the so-called better classes of natives. The chest measurement did not average over 28 inches, nor the expansion more than an inch. Although they were mere boys, they showed evidence of having committed sexual excesses. From the foregoing it will be seen that the native is in quite as much need of a physical education as a mental one, and unless that is provided for no marked improvement in his condition can be expected.

The lack of adequate and proper medical assistance in the provinces for the Americans who reside there has been again brought to the attention of the authorities. The lot of the white man in the outlying districts of the Philippines is indeed a hard one. There is not sufficient work to justify an American physician to settle in the provinces, unless he can hold some governmental position which will aid his income. The Insular authorities are not always in position to make such appointments and for that reason many hardships will no doubt have to be endured before better arrangements can be made.

Dr. E. E. Tyzzer, of the Harvard Smallpox Commission, left for the United States on the transport *Sherman*, which sailed from here December 15.

Assistant Surgeon M. K. Gwyn, of the U. S. Public Health and Marine Hospital Service, who has served in the Philippines for more than three years, has been ordered to return to the United States.

GEHEIMRATH DOCTOR DETTWEILER.

To the Editor of the Medical Record:

Sir: By the presentation of the portrait of Dr. Dettweiler to the New York Academy of Medicine our eminent phthisiotherapist has added to his numerous and valuable contributions to this subject. In this workaday world—in this age of haste and rush, immediate achievement alone appeals to our hurried observation. The lessons of a life like Dettweiler's—the history of his achievements in a field requiring cultivation with patience and self-sacrifice, demand more than a passing notice. It is therefore eminently wise and proper that the counterfeit presentment of the man who has placed phthisiotherapy upon a permanent basis shall grace the halls to which the searcher for the achievements of medicine resort.

Personal acquaintance with Dr. Dettweiler confirms all that Dr. Knopf has so well said. During an interview in 1896 on the subject of Phthisiotherapy, which was replete with instruction and pleasure, I was impressed by his hope-inspiring manner, and by the geniality and humor which brightened the discussion of a pathetic subject. Noticing on the wall of the Liegehalle some verses worked in colored wool contained in a frame, I asked their purport. The genial doctor replied that they were a gift from one of his patients who had well learned the lesson of patience and hope which he endeavored to inculcate by precept and example in his institution. The lines read:

In dem Tempel der Bacille
Herrsche musterlose Stille
Walte Lust und Heiterkeit
Dann ist die Heilung nicht mehr weit.

Freely translated this "motto" would read:—

In the temple of Bacillus
Must reign calm and perfect stillness
Must reign [illegible]
Then the cure is very near.

The great [illegible] (rest, [illegible] and moral), fresh dry air continuously inhaled night and day, in fair weather or foul, correct breathing, [illegible] cough, free and appropriate nutrition, graduated exercise in the absence of fever, judicious hydrotherapy in appropriate cases—the man who has brilliantly illustrated these basic therapeutic principles in his own practice—has passed beyond. May his lessons and his example endure forever for the relief of human suffering and the glory of Medicine!

Simon Baruch, M.D.

Hotel Majestic, New York.

EXAMINATION OF THE SIGHT AND HEARING OF SCHOOL CHILDREN IN VERMONT.

To the Editor of the Medical Record:

Sir: Your readers will be interested to know of an act just passed by the legislature of the State of Vermont [see page 221], making it obligatory throughout the state that all public school children shall have their eyes and ears annually examined by their teachers. The State of Connecticut passed a similar law some three years ago, but the one passed in Vermont is better. It is hoped that the action taken by these two legislatures will be followed by similar acts in other states.

Frank Allport, M.D.

92 State Street, Chicago.

Progress of Medical Science.

[From the Post-Graduate Medical Journal, January 25, 1905.]

The State's Relation to the Epileptic.—Owen Copp refers to the action of the London School Board, under whose direction Dr. Shuttleworth, in 1900 and 1901, examined all epileptic children of school age known to its officers. He found a ratio of about 1 to 1,000, and reported that of these defectives, "17 per cent. seemed fit to continue in normal schools, 27.5 per cent. were so far mentally impaired as to require instruction in 'special classes' for defective children, 40 per cent. required to be cared for and taught in a residential school for epileptics, and 15.5 per cent. seemed unfit for any education, requiring only medical and nursing care." Since this investigation, a large number of children who had formerly been kept at home because they suffered from fits, are now attending school. On the basis of this report, Massachusetts should have about 500 epileptic children of school age. The effort to bring such children as are suitable into schools would seem to be the duty of public school committees. The writer declares that the state should supplement these efforts by providing: (1) A center for study, research and teaching in relation to epilepsy, well officered and equipped, to afford scientific treatment to patients both within its care and at home, through advice to indigent parents and friends who may wish to avail themselves of the aid, and, in conjunction therewith, schools for elementary education, manual training and persistent drilling into habits of doing simple, every-day acts of helpfulness to the family or the institution. (2) Colonies, independent or associated with such a center, which the adult epileptic, thus trained, may enter, finding a home in place of isolation in society, and industrial opportunities graduated to his capabilities, under conditions suited to his peculiarities and the utilization of his productive energy. (3) Custodial provision for the infirm, intractable and insane epileptic. The successful management of this policy would offer a most important check to heredity transmission of the degenerative taint. There will always be a certain number of these unfortunates in the community without protection. The public are beginning to wake up to the danger to the state from these defectives, and several states have already made restrictive and punitive legislation against the marriage and illicit relations of these individuals during the child-bearing period.

The Treatment of Hemorrhoids by the General Practitioner.—T. Chittenden Hill believes that the general practitioner should be able to successfully treat the more common rectal diseases. Hemorrhoids are more frequently met with than any other rectal disease. There are two general classes—external and internal. Of the former

external connective tissue hemorrhoid. The treatment of the thrombotic hemorrhoid is simple. An injection of eucaine, 1 per cent., is given, very superficially under the skin. The injection should go slowly over the whole top of the tumor well into the anal canal, but not into the swelling. With a curved bistoury the base of the swelling is transfixed, and the cut is made outward. The clot usually expels itself, but sometimes curetting is necessary. When the connective tissue hemorrhoid is acutely inflamed and the external sphincter is not hypertrophied, a palliative course is indicated. After the acute symptoms have subsided, an injection of 1 per cent. solution of eucaine is given, and the hemorrhoid removed with a pair of curved scissors. The writer calls attention to the fact that the great majority of cases of internal hemorrhoids can be operated upon under local anesthesia or otherwise satisfactorily dealt with. He believes that in properly selected cases, where the external sphincter is somewhat relaxed, or can be dilated so that the tumors are exposed for injection, perfect results may be expected from the injection method. When, however, the hemorrhoids are not very large, or over three in number, they may be treated radically and in less time by the ligature. The after-treatment of these cases demands careful attention. The bowels as a rule should be confined for forty-eight hours, and then cascara sagrada should be given in order to secure daily evacuations. The anal region should be kept scrupulously clean. Good drainage should be secured, and the necessary topical applications be made to induce rapid healing. If an irritable or hypertrophied sphincter gives pain, both layers of the muscle should be completely divided under eucaine. The internal sphincter should be carefully guarded, as otherwise incontinence might follow.

New York Medical Journal, February 4, 1905.

Some Observations on the Diagnosis of Renal Calculus with Special Reference to Diagnosis by Means of the X-Ray.—A. B. Johnson details his experience based on the examination of 125 patients. In thirty of these a positive diagnosis was made by means of one or more plates, and the presence of stone was confirmed by operation. In twenty-six the deposits were in the renal pelvis or extreme upper end of the ureter; in four in the pelvic portion of the ureter. The author's conclusions are as follows: The positive diagnosis of kidney stone by the *x*-rays is reliable and of great practical value. The negative diagnosis of kidney stone by the *x*-rays is reliable and valuable up to a certain limit. If pictures of a proper quality are obtained, calculi of oxalate of lime and phosphates can be excluded. Pure uric acid calculi cannot. Pictures of a proper quality can be obtained with ease in children and slender adults of both sexes. Such pictures can usually be obtained by repeated trials in well nourished adults. When patients are unusually stout, when the abdomen is very thick and the buttocks are large, the conditions are extremely difficult, and only occasionally will a satisfactory result be obtainable with the present form of apparatus.

The Practical Value of Litten's "Diaphragm Phenomenon" in Diagnosis.—W. N. Berkeley describes this sign as the "visible descending and ascending wave associated with the respiratory movements of the diaphragm in the lower zone of the thorax." It may be referable to vacuum traction by the pulmonary margin or to the diaphragm itself. It occurs in from 85 to 90 per cent. of all healthy persons. It may be increased, diminished, or absent. It is best elicited by having the patient on the back with the knees toward a good daylight, head flat, and limbs extended. In this position a deep breath is taken. Berkeley concludes that to students in physiology, the phrenic wave is useful as a demonstration of the respiratory movements of the diaphragm. When unbroken and over three inches in extent on both sides, it is a good indication of healthy lungs, and should be incorporated as such into life insurance examinations. As an easy and practical substitute in many cases for the expensive and laborious *x*-ray examination of the [illegible] of the middle, which such an examination is desired. When diminished markedly on both sides low down in the thorax, and more marked behind [illegible] sign of asthma and emphysema. When absent or nearly absent on one side only, it is a useful confirmatory sign of a variety of conditions which may be suspected from other signs, particularly pleurisy and early tuberculosis. When absent on both sides no conclusion of any kind [illegible], unless the patient has been previously known to have had good waves.

Dry Gangrene Following the Application of Carbolic Dressing Covered With Oiled Silk.—V. Kenerson's patient applied a 1-50 carbolic solution to abort a felon. In a few hours the finger appeared blanched, and the solution was halved in strength. Then, contrary to orders, oiled silk was applied over the dressing and kept on over night. Next day the finger was blanched and numb, but could feel pressure. Twelve hours later the nail was black, the skin dusky over the silk-covered area. Proper measures led to a restoration of circulation in nearly all the proximal joint, but not in the distal joint, in which dry gangrene followed, the skin all coming off and muscles separating on the eighth day. Amputation was later done at the tip of the first pharnygeal joint.

Medical News, February 4, 1905.

Partially Afebrile Estivoautumnal Malarial Infection Having Its Origin in New York City.—J. L. Pomeroy reports this case. The patient, a man of 41 years, an Irishman by birth, entered the City Hospital of New York in November, 1904. The patient had never been outside of the city since his immigration fifteen years before. He was a longshoreman. His family history was negative, and his habits were good. His present illness had lasted over a period of four years. It began with chills and sweating. The first attack lasted about three weeks, during which time he was bedridden and his skin became yellow. He was told that he had malaria, and was given some pills. His recovery was slow. From time to time he had chills followed by sweats, but they were very irregular. Following a course of pills he would improve. His loss in weight was marked. Three weeks before entering the hospital, the chills and sweats recurred with renewed severity. The chills were very irregular, often occurring without being followed by a definite sweat. Again, the reverse would be the case. But the temperature was normal both before and after chill, not going above 99° F. Examination of the blood revealed the presence of beautiful crescentic and ovoid bodies, which were always extracellular. Examinations made during the afternoon showed a preponderance of the ovoid forms. The crescentic bodies were always deeply pigmented. They seemed to be more numerous during the forenoon. No other kind of plasmodia was noted. Smears were made every two hours to determine this. Jenner's stain was used in all examinations. The white blood count was 7,000. The urine showed faint traces of albumin and no sugar. A few granular casts were found after centrifuging. Shortly after his admission to the hospital, the patient was placed upon quinine sulphate in perforated capsules, grains fifteen, every four hours, and one-half ounce of Warburg's tincture, before means, to stimulate his appetite. Saline catharsis was used to relieve the constipation from which he suffered, and to increase elimination. After twenty hours there was marked improvement; the sweats became less frequent, and the strength and appetite increased. The temperature, which had been normal, now ran as high as 100.2° F. A week after treatment had been instituted, he was able to be removed to his home. No more malarial parasites were found in his blood.

A Case of So-Called Traumatic Asphyxia.—Randolph Winslow describes the appearance of a man, aged 22 years, who had been caught between the ceiling and the top of an elevator. He was forcibly bent down so that he sat on his heels, while his head was forced down to the roof of the car. He was kept for some minutes in this position. He felt as if his head and chest would burst, and he could not breathe. He did not lose consciousness, but suffered considerable pain. The fourth, fifth, and sixth ribs were broken, and there was some emphysematous infiltration of the subcutaneous connective tissues. The sight and hearing were not impaired. There was an extensive extravasation of blood under each conjunctiva. The most remarkable feature of the case was a bluish discoloration of the head, face, and neck to the level of the cricoid cartilage, or the collar line. This discoloration looked as if he were cyanosed, but it stopped short at the point mentioned. It was punctiform in character, like the eruption of scarlet fever, but blue instead of red. The head and face were swollen. The discoloration did not disappear or materially change its color upon pressure. The temperature rose to 100.8° F. on the day of the accident, but dropped to normal in three days. The patient was out of bed in a week, and left the hospital in twelve days. The skin gradually faded. None of the changes seen in ordinary ecchymotic conditions were seen, except in the bruised area and in the conjunctiva. The treatment consisted of the application of an ice-cap to the chest, and subsequently adhesive strips with enough morphine to relieve pain. The condition described is one of the rare results of a forcible compression of the thorax, and has been called traumatic asphyxia. A few cases only have been observed in the living person. The cause of the blue discoloration was supposed to be hemorrhage, but microscopical examination has proved that there was no extravasation of blood, but a dilated condition of the capillaries from overdistension. Skin taken from the present case showed the capillaries in places more or less distended with blood, but no blood was found anywhere in the tissues outside of the blood vessels. Very few cases of this nature have been reported.

American Medicine, February 4, 1905.

Rectal Alimentation.—Edsall and Miller refer to the literature and their own previous work which indicate that nutrient enemata are very poorly absorbed and that exclusive rectal alimentation is incapable as a rule of maintaining a nutritive balance. They report a series of experiments in which they carried out rectal alimentation in dogs and also determined the absorption in isolated loops of intestines in dogs; and further they report an absorption experiment in a human being. This work was done in order to determine in how far it is possible to improve fat absorption by giving the fats in the form of soaps, or by giving them in an artificial emulsion, when the emulsion is so prepared that it will not readily be broken up in the bowel. Their results are such as to convince them that it is impossible by any methods now available to administer successfully sufficient soap to make it of decided nutritive value. Their results with an artificial fat emulsion, particularly in the human subject, were somewhat encouraging and they believe that by further study it may be possible to increase the clinical value of nutritive enemata though it is still a question whether it will ever be possible to maintain nutrition in this way.

Diet After the Age of One Year.—J. P. Crozer Griffith discusses the difficulties attending the feeding of healthy children after the age of one year. Weaning should be commenced at about the age of ten months, only one bottle of food being given at first, and this of a strength less than mother's milk, since cow's milk is a new substance to which the child is unaccustomed. Gradually the number of bottles and the strength of the mixture should be increased, until at the age of a year the food should consist of milk but slightly diluted. Systematic weighing, twice weekly, is very important during this period in order to anticipate any decided falling off in the normal gain in weight. Some form of gruel should be added to the bottle for the purpose of accustoming the infant to the digestion of starch, since it will be taking this in large quantities soon. At the age of a year feeding with the gruel or barley (not oatmeal) begins, this being given in the middle of the day. Later this is taken at breakfast time, and rice, bread or hominy grits with beef juice is given for dinner. A plain dessert is added soon, such as rice pudding or junket. Eggs may be tried cautiously at fifteen months. Potatoes and meat are not given until eighteen months. The author gives diet tables for children of different ages up to three years, and a list of permissible and non-permissible articles of diet for periods beyond this. In concluding he emphasizes particularly certain general rules which seem to him of importance. Among these are: That milk must continue throughout early childhood to form the chief article of diet; that broths are serviceable as food only through the cereal addition to them; that although rashness on the part of the mother in experimenting on new foods is to be condemned, too great caution resulting in too long a continuance with insufficient food is equally harmful; that children in the second year are fed far too frequently; that too much starch is a more frequent cause of illness than too much meat, and that the age and need of the child, rather than the teeth, are to be the guide in determining when the giving of meat should be commenced.

Acute Postoperative Thyroidism.—S. Edward Sanderson, after comparing acute thyroidism to exophthalmic goiter, the author reviews the theories of the etiology of the latter. He cites all the cases found in the literature of the class he terms "acute postoperative thyroidism," giving five, and reports a case occurring in his own practice. His patient was a young woman of twenty. The trouble followed an operation for chronic appendicitis. Her most marked symptom was the tremendous heart action, with a rate at times more than 200, the force was so great as to make the heart distinctly heard at the foot of the bed. The patient recovered; due partly, possibly, to the use of cactus grandifloris.

Journal of the American Medical Association, February 4, 1905.

The Nature of Traumatic Sclerosis.—A. C. Brush states that diffuse violence to the cerebrospinal axis causes the condition known as concussion or commotion. In this condition there may be localized hemorrhages, lacerations, or contusions of nerve tissue, multiple minute hemorrhages or thrombi scattered throughout the cerebrospinal axis, general edema, distension, and infiltration of the blood vessels; that from these lesions the following secondary changes may occur: The vascular hyperemia and infiltration of the vessel walls not only decreases the amount of nutrient lymph supplied to the nerve tissue, but also interferes with its return by a proliferation of the adventitia and a collection of débris and leucocytes in the perivascular spaces. This deprives the nerve cells of nutriment, and at the same time they are poisoned by waste products. Observations show that the nerve cells die in a few hours when their nutrition is entirely cut off, and that defective nutrition causes the same changes after longer periods; the degenerative changes beginning in the chromatic parts of the cell, and finally destroying the nucleus. The final result, therefore, is areas of degeneration, or of sclerosis, and possibly arteriosclerosis. The autopsy findings in five personal cases are given. In general it may be said that traumatic sclerosis is an organic disease of the cerebrospinal axis, that trauma is a competent producing cause, and that it is not merely a type of multiple sclerosis but a distinct pathological entity.

Prevalence and Prophylaxis of Pneumonia.—E. F. Wells contends that this disease is increasing, both in deaths per thousand of the population and in percentage of total deaths. Charts compiled from the health records of several cities are presented in support of this view. As to prophylaxis, he gives the following advice: For the individual the nasal, pharyngeal, and oral cavities should be kept as clean as possible, and especially free from accumulations of mucus. When it has been demonstrated that such secretions contain the pneumococcus these efforts should be particularly well directed and maintained. In coughing and sneezing a protective cloth, preferably moistened, should be held before the mouth and nose. This is especially necessary in the case of pneumonic patients and in those harboring the pneumococcus. The sputum and other secretions of the respiratory tract of such persons should be destroyed before they have become dried. Individuals should, so far as practicable, keep out of range of the extruded pneumococcus-laden secretions of infected persons. For the public: The above advice, properly formulated into plainly and succinctly stated rules, should be widely and persistently circulated by the communal health authorities among the laity, and practicing physicians should be furnished a supply of these rules, neatly printed and without imprint, with the request that they give it as their instructions to their patients and clientele. And further, by every means, the interest of physicians and humanitarians in this subject should be aroused and fostered. For this purpose special societies and committees might be formed for the purpose of studying the problem and furthering the efforts of the various health bodies, as has so successfully been done in the case of tuberculosis.

The Relation of the Internal Secretions to Epilepsy, Puerperal Eclampsia, and Kindred Disorders.—The paper of C. E. Sajous is a continuation of his previous studies on the functional relationship between the adrenals, the pituitary body, and the thyroid. He believes that in the clinical states named we are dealing with two sources of convulsions. First, a toxin in the plasma circulating in the nervous elements, and second, an excess of activity in the pituitary body, leading to a correspondingly marked oxydation in all organs, including the muscles. The first is certainly pathogenic, while of the second, the most we can say is that it is an exaggerated manifestation of normal functional activity, and is perhaps protective. For therapeutic measures, the author would advise lines of treatment which increase the functional activity of the adrenal system, doing precisely what thyroid extract does after the removal of the thyroid. Hence there is logic in the increasing tendency to use iodine, mercurial inunctions, and other remedies which tend powerfully to increase oxydation and general metabolism by enhancing the functional activity of the organism's protective system.

The Lancet, January 21, 1905.

Suppurative Pericarditis.—One case is reported by R. W. Murray, his patient being a boy of 13 years. One week before admission to hospital, he presented, without apparent cause, a suppurative arthritis of the left ankle and of the metatarsopharyngeal joint of the great toe of the same side. Operation revealed the focus of infection to be an acute osteomyelitis of the lower end of the tibia. Examination of the cardiac region led to a suspicion of pus in the pericardium. This suspicion was confirmed by the exploring needle, and the pericardial sac was opened in the fourth left space, three-quarters of an inch from the margin of the sternum. Recovery ensued, though some difficulty was experienced in properly draining the sac. The author believes that the association of acute osteomyelitis and suppurative pericarditis is not uncommon. Increased cardiac dulness is to be looked on as the most reliable sign of chest involvement. The best drainage is obtained by opening in the costoxiphoid space, removing a portion of the seventh costal cartilage, and then keeping the patient propped up in bed. Gentle irrigation may be employed if necessary. This was successfully done in the author's case.

A Case of Acute Leukemia.—A case occurring in a boy of 17 years is reported by W. M. Stevens. The salient features were as follows: (1) The entire illness lasted only nineteen days; (2) the mode of onset and general symptoms (headache, malaise, continued fever) suggested typhoid, or tuberculosis, malignant endocarditis, or a septicemia; (3) splenic enlargement not noted until the thirteenth day of the disease. The organ was only slightly

enlarged, and it was very firm and not tender. The splenic enlargement, associated with pallor and with purpuric spots on the flanks, suggested some diseased blood condition. (4) Glandular enlargement. Enlargement of the lymphatic glands did not make its appearance until after the thirteenth day, by which time the diagnosis had been made by blood examinations. (5) The latter showed 1,620,000 red cells per c.c., and 920,000 white cells, the excess of the latter being made up entirely of large lymphocytes. (6) The continued and painful priapism giving rise to great distress.

Some Clinical Uses of Iodic Acid and the Iodates.—Personal experience with these remedies is given by W. M[illegible]kie. He has for some time used the calcium iodate in fine powder as an application to all cicatrising surfaces, leg ulcers, in a gauze dressing after major operations, etc. In minor operations, a liberal use of the powder often leads to healing under a dry scab. A warm saturated solution has been used as a vaginal douche, and as a bladder irrigant; also as an irrigant for chest empyemas. As a mouth wash, iodic acid is preferable. In an ointment of ten grains [illegible] capitis. In emulsion it is good for tuberculosis joints and cavities. It is apparently a valuable gastrointestinal anti- [illegible] for which it is, in a general way, a substitute. More recently the author has been using the iodic acid. It is a more powerful deodorant than potassium permanganate, and is of special value as an irrigant in ozena. The iodate of zinc may be used when a stronger action than that of the calcium salt solutions is required. Another valuable preparation is the subiodate of bismuth, used as a general dusting powder. A mercuric iodate [illegible] locally for sycosis, in the proportion of twenty grains to the ounce of ointment. Good results were secured in tinea barbæ. Illustrative cases are given of the effects of these remedies in the diseased states above enumerated.

Clinical Observations on a Kidney Which Contained More Than Forty Thousand Iridescent Calculi.—J. Bland-Sutton reports this interesting case. The patient was a printer, thirty-eight years of age, who had had pain in his right loin for a period of fifteen years. He had no remembrance of passing a calculus, although the small spherical bodies found in his kidney seemed to be made to traverse the ureter. The sac which contained them appeared to communicate with the renal pelvis by a small orifice, barely allowing the passage of a small bristle. The urine contained microscopic traces of blood and pus cells, which increased markedly after exertion. It is probable that the sacculus containing the stones was of congenital origin. The retarded flow of urine through the pouch was a means of adding to the number of the concretions, while the anatomical conditions of the sacculus hindered them from escaping. The kidney was found at operation to be much enlarged and very movable and its lower half stuffed with calculi. It was completely disorganized and was removed. The calculi really fall into two groups: The first group consists of ten calculi of varying sizes and shapes. The largest resembles a child's astragalus with well-marked facets. The smaller calculi are fairly spherical, and all of a bright color, like old gold. It is probable that 40,000 is far below their real number. They consist chiefly of calcium phosphate and calcium oxalate, and there is epithelial matter also in the concretions, but this is more abundant in the husk than in the kernel. The iridescence of these calculi is as remarkable as their great number.

Cancer of Gall-Bladder Due to Irritation of Gallstones: Cholecystectomy and Partial Hepatectomy.—J. Hutchinson had charge of this interesting case. The patient was a woman aged sixty-six, who had been suffering from a collection of gallstones for over two years. During this time there were repeated attacks of abdominal pain, accompanied by retching and followed by sweating. Constipation existed and the stools were of light color after the attacks. Jaundice was present. A deep-seated tumor could be palpated in the right hypochondrium. The dullness over it was continuous with that of the liver. At operation, over eighty calculi were removed from the gall bladder. The fundus was found to be thickened and hard from a carcinomatous growth, with small papillary projections of the mucous membrane. The cancer had extended into the liver above where it formed rounded lumps, but the infiltration seemed to be limited to the immediate neighborhood of the gall-bladder. A wedge-shaped piece of the liver with almost the whole gall-bladder was excised. The sides of the hepatic wound were brought together, the neck of the gall-bladder was sewn to the peritoneum, and two drainage tubes were inserted. The patient recovered from the shock of the operation, but developed an acute dilatation of the stomach. With treatment this subsided. The wound required daily attention. After the fourth week the temperature became hectic in type. Four months after the operation there was evidence of extensive recurrence of cancer in the liver. The writer does not think it would have been possible to make a correct diagnosis in this case before operation. There was no cholecystitis, although the gall-bladder was packed with stones, and the fundus invaded with cancer. Hutchinson believes that there can be no doubt that the existence of the calculi preceded for a long time the development of cancer.

Reasons for Abandoning the Uric Acid Theory of Gout.—Chalmers Watson emphasizes several points in connection with his investigations in this subject. He has proved that uric acid is normally present in the blood of birds. His results negative the view that uric acid is normally formed in the kidney, and they indicate that the theory of the renal origin of gout, so far as this rests on the absence of uric acid in the blood of birds under normal conditions, cannot be entertained. It has been found that in a number of diseased states which have no known relationship to gout, uric acid is present in weighable quantity in the limited amount of blood or pleural fluid examined. There is no striking change in uric acid elimination in acute gout, thus one of the main premises of the uric acid theory is erroneous. In the study of the histological appearances of the tissues in gout, it has been shown that the pathological pictures are strikingly similar to those seen in chronic infective diseases. Uric acid is regarded as the feature which gives the inflammation its specific character. From the clinical standpoint, the manner of onset, the course of the temperature curve, the changes in the blood indicating disturbances of the marrow function, and the marked liability to relapses, all are strikingly like the phenomena observed in an acute infective disorder. The author believes that there is an infective element in the disease; and that uric acid is the feature which gives the inflammation its specific character. The chief source of infection is the alimentary tract, and an injudicious dietary acts mainly by its influence on the bacteria present in the digestive tract. The importance of the hereditary factor in the disease is not minimized. As to evidence for or against the theory presented in this paper, the writer thinks it should be looked for along the following lines: The influence of a meat diet and a carbohydrate diet on the digestive secretions and on the ductless glands, special attention being paid to the thyroid gland and the bone marrow. It would be well also to repeat Ebstein's experiments with the aid of bacteriological methods.

A Note on Senile Symmetrical Atrophy of the Skull.—F. Parkes Weber refers to a curious condition of symmetrical circumscribed thinning of the parietal bones, generally regarded as a form of senile atrophy of the skull. But it sometimes occurs in younger persons. A number of cases have been collected which have been associated with melancholia. The writer thinks that this condition is probably due to a process of lacunar absorption accompanying senility or other chronic states of depressed nutrition. Not every senile change is present in every old person, while on the other hand some senile changes develop relatively early in certain individuals through heredity, or wasting diseases, or chronic causes of depressed nutrition, including mental causes. It is known that "brown atrophy" of the heart, similar to that found in very aged persons, is sometimes met with in younger persons dying of cancer and other chronic wasting disorders. The lacunar absorption which causes atrophy of the outer table in the parietal bones is probably due not alone to senility, but intimately connected with it. Senile atrophies are nearly always either general or symmetrical in distribution. Their localization is probably to be explained by parts being selected which are no longer being much used, and which are of least vital importance to the organism. Symmetrical atrophy of the parietal bones is in a position where there is no muscle pulling; this part also is mechanically of relatively little importance for maintaining the strength of the brain case and its safety from concussion.

Atropine in Inebriety.—A. P. Hope Simpson cites the history of a case of inebriety in which atropine treatment was used. The patient, a man of 48, began to drink heavily nearly twenty years ago. Seven years later he reformed and remained a sober man—with several relapses—until the fall of 1903. He became more addicted to his old habits at this time than ever before. The writer persuaded him to try the atropine treatment, leaving a bottle of whisky in his bedroom, and giving him permission to take any alcohol he wished. The treatment was as follows: (1) Frequent and good meals every four hours. (2) Combined hypodermic injection of atropine sulphate and strychnine nitrate in the following quantities: First week, atropine 1-100 gr., strychnine 1-60 gr., t.i.d. Second week, atropine 1-50 gr., strychnine 1-30 gr., t.i.d. Third week, atropine 1-50 gr., strychnine 1-30 gr., t.i.d. Fourth week, atropine 1-100 gr. bis in die. (3) A mixture containing fluid extract of cinchona, spt. ammon. aromat., and spt. æther, chlor, thrice

daily. (4) The thorough regulation of the bowels. The writer calls attention to several points in the case: (1) On the second and third days the patient indulged, with permission, in a bottle of beer. (2) During the second and third weeks he suffered from interference with accommodation and dim vision, owing to the dilatation of the pupils. He also complained of thirst, but this symptom ceased to annoy him when he was given potassium chlorate lozenges. (3) At the close of the third week he began to twitch in the hands and face, and the strychnine was immediately stopped. He has now been living his ordinary life since the middle of June, and not only has no taste for liquor, but even has a marked aversion to it. He is now a hard-working, cheerful member of society.

Berliner klinische Wochenschrift, January 16, 1905.

Immunization Against Tuberculosis.—Baumgarten and Hegler describe a continuation of their efforts to produce experimental immunity against tuberculosis in animals. The endeavor to produce immunity in rabbits and guinea pigs by means of the serum of cattle immunized against tuberculosis was unsuccessful, so the attempts were repeated on calves, as these seemed to offer a more promising field for the experiment, since no foreign amboceptors could be present to complicate the question. The serum used was obtained from an animal which after inoculation with human tubercle bacilli, had been five times subcutaneously infected with virulent *perlsucht* material without giving any evidence of disease or positive tuberculin reaction. In order to test the efficacy of this serum, three calves of equal size and about three months old were selected. None of these reacted with tuberculin. Calf No. I received by cutaneous injection in the neck, 82 c.c. of the immune serum in several doses, and then, like the other two animals, was injected with 5 c.c. of virulent *perlsucht* material. Calf No. III served as a control, and calf No. II was given in all 70 c.c. of protective serum in several doses. Both of the latter two animals were killed shortly before they succumbed to the infection, and were found thoroughly permeated with tuberculous lesions. Calf No. I, which had been given the prophylactic injections of immune serum followed by the same amount of *perlsucht* bacilli as had sufficed to kill his comrades, was slaughtered several months later, and showed no lesions whatever, except a single slightly suspicious lymph gland. Although no conclusions can be drawn from a single experiment, it is highly suggestive that the unimmunized animal and the one receiving the antiserum only after the infection, should have succumbed, whereas the other animal was fully protected against the otherwise fatal dose by preliminary treatment with the antiserum.

Münchener medizinische Wochenschrift, January 17, 1905.

The Agglutinating Power of Typhoid Serum for Paratyphoid and Allied Organisms.—Grünberg and Rolly describe a series of observations on the agglutinating properties of serum obtained from forty different typhoid patients. In thirty-two of the number it was possible to isolate typhoid bacilli from the blood, and the other eight were typical from the clinical point of view that there can be no question as to the diagnosis in any of the series. It was found that neither the intensity of the reaction, nor the number of typhoid bacilli in the blood had any relation to the severity of the case, nor did these two factors appear to exhibit any interdependence. In 70 per cent. of all the cases the paratyphoid bacilli were also agglutinated, and in 35 per cent. the reaction was more pronounced for these than it was for the typhoid organisms. The possibility of mixed infections in these cases was ruled out by the presence of pure cultures in the blood. In twelve out of twenty-two cases (55 per cent.) a positive reaction was obtained with the colon bacillus in a dilution of 1:30. Two cultures of the organism were used, and in some instances the one, and in others the other organism responded. At a dilution of 1:30 *B. enteritidis* of Gärtner was agglutinated in all cases, and in 22 per cent. of the cases the agglutinating value was higher than for the typhoid bacillus. The results obtained for the paratyphoid bacillus and *B. enteritidis* of Gärtner were not at all in harmony, so that this seems to furnish another argument against the claim of identity between the two that has been set up by some observers. Tests were also made with *B. botulinus* of van Ermengen, but at 1:30 agglutination was present in only 14 per cent. of the twenty-one sera tested.

Ficker's Method of Diagnosis in Typhoid.—Selter, Flatau and Wilke, and Eichler contribute three articles dealing with the efficacy of the sterilized culture described by Ficker for use in carrying out the agglutination reaction for the diagnosis of typhoid, instead of the usual Gruber-Widal technique. The first named author says that the method is distinctly useful, and for practical work is fairly reliable, but that it cannot hope to replace the older procedure. According to his observations, carried out on twenty-four sera, the Ficker reaction does not appear so early nor last so long as the Gruber-Widal agglutination. The method is rather expensive, involves a long time of observation before the result is definite, requires a separate outfit for each serum if several examinations are to be made simultaneously, and is not available if, as is often the case, the paratyphoid organism is to be ruled out. Flatau and Wilke are less critical, and consider that Ficker's method is in all points a satisfactory substitute for the Gruber-Widal. In some instances it even seemed more sensitive than the microscopic method, and is preferable on account of the smaller amount of apparatus that it requires. Eichler desired to test the keeping qualities of the reagent, so took a sample with him on a six months' voyage through the tropics. Tests made during the trip and after his return showed that the preparation had lost none of its delicacy of reaction, and the author warmly recommends it for use on shipboard, on account of the simplicity and ease with which the reaction may be carried out, as cultures, laboratory facilities, microscope and incubator may all be dispensed with.

Annals of Surgery, January, 1905.

Some Considerations Regarding Wounds of the Liver.—Two cases are detailed by B. T. Tilton, who gives a general description of this class of injuries. Of his own cases, one recovered and one died, the former being a case of gun-shot wound and the latter showing on laparotomy a large, ragged tear, six inches long, on the right lobe. No cause therefor could be learned. From a review of the subject Tilton notes that the prognosis of the severer cases of wounds of the liver alone has improved of late years, especially under early operative treatment. Many cases must necessarily, of course, be promptly fatal from shock or hemorrhage or from associated injuries of other organs. Many others can be saved by operation which would otherwise die from hemorrhage or some complication. The treatment of all open injuries should be early laparotomy for the purpose of hemostasis, thorough examination, and prevention of infection. As regards subcutaneous ruptures, the mild cases without marked symptoms of collapse or internal hemorrhage should be treated expectantly. Cases in which there are marked collapse or signs, local or general, of internal hemorrhage should be treated by early laparotomy, with suture or packing of the wounded liver.

The Surgical Treatment of Chronic Dyspepsia Due to Defective Drainage, and Chronic Inflammation of the Stomach Resulting from Gastric Atony and Dilatation.—The main thesis of J. G. Sheldon is that a not infrequent cause of disagreeable and long-standing dyspeptic symptoms is gastric atony followed by chronic gastritis, moderate dilatation, and defective stomach drainage. These conditions give rise, when of long duration, to almost continuous dyspeptic symptoms associated with secondary neurasthenia and chronic constipation. Gastroenterostomy with closure of the pylorus will give these cases complete and permanent relief, not only from their stomach symptoms, but also from the neurasthenia and constipation. The clinical histories of these cases are given in detail: in all of them the result was successful so far as the relief of symptoms was concerned. The diagnosis of the condition with reference to indications must be made by exclusion and is not always successful. In one of the author's cases in which he expected to find only a dilated and atonic and chronically inflamed stomach, he discovered a beginning carcinoma of the pylorus. He did a pylorectomy eighteen months ago, and the patient still remains well. In two other cases a definite benign stenosis of the pylorus was found. In a fourth case, a cirrhosis of the stomach was present.

Penetrating Wounds of the Abdomen.—F. L. Hupp reports six cases due respectively to stab wound (operation and recovery); pistol shot (no evidence of abdominal penetration, expectant treatment, recovery); pistol shot (operation, recovery); pistol shot, four cases (operation, three recoveries and one death). He offers the following conclusions: First, recognizing that visceral injury follows in 97 per cent. (Douglas) of penetrating gunshot wounds of the abdomen, immediate laparotomy, with a liberal incision, should be practised in every such case. Second, the symptoms exhibited by the patient, the location of the wound, and the course of the bullet should rather be used for determining the presence or absence of penetration, as the use of the probe is not only harmful, but may lead to false conclusions. Third, well-directed drainage in all cases in which there has been visceral perforation is of the greatest importance.

Volvulus of the Cecum.—E. M. Corner and P. W. G. Sargent analyze fifty-seven cases of this affection, including five coming under their personal observation. They are inclined to believe that some attacks of recurrent abdominal pain with fulness and tenderness in the right iliac fossa, constipation, and vomiting, but without fever, which come on after exertion or other slight cause, passing off in a

few hours, and which are generally referred to the appendix, are due in reality to conditions particularly involving the cecum. Volvulus of this part of the bowel seems to be three times as frequent in men as in women. Age limits in their series are nineteen days and between seventy and eighty years. Of the fifty-seven, operation was done on nineteen successfully, on twenty-one unsuccessfully, while the remainder died without operation. Their anatomical classification is (1) circular rotation, *i.e.* about one fixed point; (2) elliptical rotation (about two fixed points); and (3) axial, that is, about the longitudinal axis. The appendix may undergo secondary inflammatory changes which may at any time become so acute as to overshadow the original cecal condition. The displaced cecum has been found in every region of the abdomen (most commonly in the left hypochondrium) and even in the sac of an inguinal hernia. The most common form occurs between the twentieth and fortieth years. In these cases the roots mesentery, instead of being localized to the origin of the superior mesenteric artery (as sometimes happens), tends to a lesser degree than normal towards the right iliac fossa. In this way the mesentery of the lower part of the ileum is relatively shorter than that of the rest of the small intestine or the cecum, and offers a more or less fixed point for the latter to rotate upon.

The Matas Operation for Aneurysm.—H. B. Gessner reports a case treated in the manner indicated. The tumor occurred in the right popliteal artery of a negro aged 32 years. It was five inches in the long axis of the limb and four and one-quarter inches transversely. Swelling and pain had lasted two months. There was a distinct history of syphilis. The operation was performed in the usual manner, the sac walls being approximated. Some ten weeks later the patient was able to be up and walk with a little assistance. The claim made for this method, viz., non-interference with the collateral circulation, seems to have been borne out by this case.

French and Italian Journals

Modifications of the Pulse Under the Influence of Coughing.—Gaultry has done some interesting work on this subject, from which he believes that the modifications of arterial pulsation due to coughing, are due not only to a mechanical action, but also to a nervous action. In normal subjects, the cough increases the frequency of the pulse and the arterial tension, and communicates to the rhythm of the pulse only a very temporary irregularity. In subjects with affections of the respiratory apparatus, the frequency of the pulse and the arterial tension are increased by coughing, and the irregularity of the ryhthm is very marked during the efforts of coughing. The duration of these modifications is longer than it is in the normal state. It increases with the youth of the individual, and with the weakness of the initial arterial pressure. In the case of whooping-cough without complications, the cough increases the frequency of the pulse and arterial pressure in a very marked fashion. In emphysematous patients, the cough increases the frequency of the pulse and the arterial pressure, and communicates to the pulse a very marked arhythmia. These modifications are less marked and of short duration in aged patients, and particularly in those afflicted with dilatation of the right heart. In pneumonia, the frequency of the pulse, which is slightly increased by coughing, persists for a long time, while the arhythmia exists only at the time of the cough. In an asthmatic attack, the cough increases the frequency of the pulse and the arterial pressure, but its effects are slight in relation to the pressure. In aortic insufficiency coughing increases slightly the frequency of the pulse and arterial tension, while arhythmia exists only at the time of the shock of the cough; the duration of these modifications is very short. In mitral insufficiency, coughing increases for some time the frequency and arhythmia of the pulse as well as the arterial pressure.—*Revue Française de Médecine et de Chirurgie,* January 2, 1905.

Hysterical Blindness.—Cabannes describes hysterical blindness as being a rare affection, but, nevertheless, clearly defined. Much attention has been given to the study of this affection in his clinic. Women are far more often affected than men—in the proportion of 85 per cent. In the majority of cases, the abolition of vision is at the onset complete and bilateral. The diagnosis of hysterical blindness ordinarily offers no difficulty: Blindness, total, bilateral, occurring suddenly, without apparent cause, associated with other symptoms of hysteria and clearly characterized from the objective point of view; by the integral conservation of the pupillary reflex; by the absence of ophthalmoscopic lesions. Certain sudden attacks of blindness observed in the course of, or during convalescence from certain infectious maladies, such as whooping-cough, typhoid fever, malaria, influenza, acute articular rheumatism, scarlatina, infectious pneumonia, have as objective characteristics: Integrity of the fundus of the [illegible] of pupillary reflex. Exceptionally, in these cases, the pupils are large and immobile. The writer considers these amauroses either as hysterical manifestations or as slight retrobulbar neurites, and amenable to cure. Simulated blindness must be taken into consideration in the treatment of these cases. The simulation of a complete, bilateral blindness is very exceptional. The prognosis and treatment of hysterical blindness are the same as those of other phenomena of this serious neurosis.—*Gazette Hebdomadaire des Sciences Médicales de Bordeaux,* January 1, 1905.

Section of the Posterior Branch of the Radial Nerve, Suture, Recovery.—Bonnet has had under his care a young soldier who had received a wound from a knife on the posterior part of the forearm. The cut had severed the posterior branch of the radial nerve in its course through the supinator brevis. A characteristic paralysis had followed the injury. Flexion of the hand and fingers with abduction of the thumb, and conservation of the movements of pronation and of supination. Bonnet saw the patient fifteen days after the accident and made the correct diagnosis. On the twenty-eighth day he decided to operate on the arm. The two ends of the nerve were easily found. They were separated by a few millimeters. The operator freshened the ends and easily brought them together, suturing them with catgut. It was some time before improvement was noticed in the function of this nerve, but at the end of three and one-half months the motor function began to manifest itself, and a month later the arm was almost normal.—*La Presse Médicale,* December 31, 1904.

Treatment of Infections Following Operation for Cataract.—A. Bourgeois always examines the eye on the day after the operation. Two sorts of conditions may present themselves: Lesions which begin in the cornea, and appear twenty-four hours after operation. These are the most grave. And those which have their origin in the uveal region, and show themselves on the fifteenth or eighteenth day. These are less grave. The treatment employed by the writer is the method of subconjunctival injections of sublimate, or better, cyanide of mercury, 1 centigramme to 10 grammes of distilled water. A few drops of the solution of cocaine,—1-20,—are added. If the infection is severe, two injections a day are given. In cases not severe, four or five injections suffice. In the severe infections, eight injections arrest the infection. The local treatment consists of atropine, belladonna frictions, galvanocauterization, and so on. These measures should not be neglected, any more than the general treatment. This method of treatment has met with excellent success.—*Recueil D'Ophtalmologie,* December, 1904.

A Case of Malignant Pustule Treated with the Anti-Carbuncle Serum of Sclavo.—Luciano Sibille records the case of a young man, a dresser of hides, aged 24, who presented himself with a pustule in the right temporal region, with a depressed black eschar in its center, and the size of a two centime piece. It was accompanied with a marked swelling of the neck, and the parotid and cervical glands were much swollen. He had fever, dry and coated tongue, and was at times slightly delirious. Thirty cubic centimeters of anti-carbuncle serum were injected into the abdominal wall. The temperature remained elevated, and another injection was given the following day, and the pustule was excised and the wound covered with an antiseptic dressing. Two other injections were given, and were followed by a gradual disappearance of all general symptoms and healing of the wound.—*Gazetta Medica Lombarda,* December 19, 1904.

Histology of Imperforate Hymen.—E. de Arcangelis has made careful histological examination of the excised portion of a hymen removed from a case of imperforate hymen, in which retension of menstrual fluids had occurred. He found the tissues to consist of two layers of epithelium separated by a stratum of ordinary connective tissue. The external layer of epithelium was similar to the ordinary epidermis, except that there were prolongations of the epithelium down into the basement layers, as if seeking to meet similar prolongations from the inner layer of epithelium. The inner layer was a stratified epithelium that was not flattened, nor, strictly speaking, cylindrical in type, but approached the cylindrical. In the intervening connective tissue were a small number of muscular elements. The inner layer of epithelium was quite different from the ordinary epithelium of the vagina, appearing as a stratified cylindrical epithelium, without any corneous layer. The author considers the peculiarities of the epithelial lining to be due to the absence of the normal conditions that obtain in a functioning vagina.—*Archivio di Ostetricia e Ginecologia,* November, 1904.

Prostatectomy.—Belfield says that the prostate should be removed only when the obstacle to urination is real hypertrophy of the prostate; when the urinary function cannot be restored by the retained catheter, etc.; and when the patient's condition warrants a serious operation.—*Colorado Medical Journal.*

Book Reviews.

Beiträge zur Klinischen Medizin. Festschrift Herrn Geheimrat Professor Senator zur Feier seines siebenzigsten Geburtstages gewidmet. Mit 2 Kurven und 2 Abbildungen in Text. Berlin: August Hirschwald, 1904.

This is a worthy addition to the large number of similar publications which have lately been dedicated to eminent men by their friends and pupils. The intense activity which has characterized Senator's life is attested by the fact that the bibliography of his published scientific disquisitions comprises one hundred and eighty-five titles. The present volume contains thirty contributions covering a wide range of subjects and for the most part of considerable interest.

Lectures on Diseases of Children. By Robert Hutchison, M.D., F.R.C.P., Assistant Physician to the London Hospital and to the Hospital for Sick Children, Great Ormond street. Author of "Food and the Principles of Dietetics." Joint author of "Clinical Methods." London: Edward Arnold, 1904.

This little volume neither pretends to be a treatise on the diseases of children, not yet to compete with the larger textbooks dealing with that subject. In it will be found a concise and reliable account of the common diseases of children. The subject is treated throughout from the clinical standpoint, hence questions of diagnosis and treatment are dealt with in some detail, and the problems of pathology are relegated to the background. The colloquial style of these lectures adds to their interest, and will ensure for the volume the careful reading that it well deserves. The book consists of nineteen lectures, covering the following subjects: Clinical examination of sick children, artificial feeding, digestive disorders, wasting diseases, tuberculosis, rickets, scurvy, dyspepsia of the second dentition, rheumatism, respiratory diseases, functional nervous diseases, paralyses, meningitis, mental deficiency, blood disorders, the diagnostic significance of some of the common symptoms of disease, medical aspect of adenoids. The volume is well printed and illustrated, is handy in size, and can be commended to the practitioner or senior student as a book of sterling merit.

Normal Histology and Microscopical Anatomy. By Jeremiah S. Ferguson, M.Sc., M.D. Instructor in Normal Histology, Cornell University Medical College, New York City. With four hundred and sixty-two illustrations in the text, many in color. New York and London: D. Appleton & Company, 1905.

The subject matter in this excellent book is thoroughly modern and is presented in clar and readable fashion, while the unusual profusion and quality of the illustrations contribute a great deal to the attractiveness of the volume. The original drawings are the work of the author, and there are also a hundred and twenty original photomicrographs. An interesting feature is the free use of drawings made from plastic reconstructions of organs, which should be of great assistance to the student in understanding the nature of such structures as the adrenals, various glands, the blood, and lymphatic systems of different regions, etc. The minute anatomy of the eye and of the ear is discussed at much greater length than is customary, and the section devoted to the nervous system is also worthy of note, both on account of its completeness and of the character of its illustrations. The bibliography is conveniently grouped by topics at the end of the volume and presents a well selected list of the more important contributions to histological literature.

Diseases of the Liver, Gall-Bladder, and Bile-Ducts. By H. D. Rolleston, M.A., M.D. (Cantab.), F.R.C.P. Physician to St. George's Hospital, London. Formerly examiner in medicine in the University of Durham, etc. Fully illustrated. Philadelphia, New York, and London: W. B. Saunders & Company, 1905.

This volume should prove a useful contribution to the literature of internal medicine and is probably the most extensive treatise on diseases of the liver yet published in English. The product of years of special activity in this field, it reflects an unusual degree of experience in a difficult but highly important branch of medical study and will undoubtedly prove of service both to physicians and surgeons. The microscopical pathology of the various disease processes is given the very prominent position it deserves, and this section of the subject matter is illustrated by a considerable number of fairly good drawings and photomicrographs. The other figures are also well chosen and for the most part portray interesting conditions, though figure 38, showing clubbed fingers, hardly seems important enough to be reintroduced fifty pages further on. Despite the author's assertion in the preface that it seemed advisable to omit the systematic bibliographies prepared for the special subjects, the references to writers mentioned in the text are unusually abundant and are fully representative of modern views. The practical utility of the volume as a work of reference is secured by a very comprehensive index.

Atlas and Epitome of General Pathologic Histology. By Docent Dr. Hermann Dürck, of the Pathologic Institute, Munich. Authorized Translation from the German. Edited by Ludvig Hektoen, M.D., Professor of Pathology in Rush Medical College, Chicago. With 176 colored illustrations on 80 lithographic plates, and 36 figures in black and colors. Philadelphia, New York, and London: W. B. Saunders & Company, 1904.

This is perhaps the most beautiful volume of the series of atlases to which it is the latest addition. The plates represent the acme of the lithographer's art and it is difficult to conceive of any features in which they could be improved. The text is simple but adequate and forms an appropriate commentary on the sections of tissues depicted. The number of the interpolated notes bears evidence to the conscientiousness of the editor's work and his additions are always to the point.

In the Year 1800. Being the Relation of Sundry Events occurring in the Life of Doctor Brush During That Year. By Samuel Walter Kelly, M. D. Chicago, Akron, O., New York: The Saalfield Publishing Co., 1904.

This is the third volume of "The Doctor's Recreation Series," edited by Charles Wells Moulton. It is more strictly a book for the doctor than were the two preceding volumes, which were rather books about the doctor, and, while of special interest to the medical man, were yet adapted to provide entertainment to the general reader as well. The present volume is too full of pathological detail to serve a useful purpose in adorning the physician's waiting-room table and diverting the patient who is dreading the ordeal of the examining-room.

The story purports to be a revised transcript of an autobiographical detail in the life of Dr. Jonathan Brush, who lived at the end of the eighteenth and beginning of the nineteenth centuries, and whose intimacy with Dr. Rush, General Knox, and other historical characters lent to his doings an importance which of themselves they might not have had. The story is well told, reminding one of Weir Mitchell, though it must be said somewhat remotely. The reader's interest in the narrative is sustained throughout, but the thought cannot always be repressed that the story would have been more artistic in its telling had it been compressed within half the compass of its four hundred and more pages and made a trifle less redolent of the shop.

How to Study Literature. A Guide to the Intensive Study of Literary Masterpieces. By Benjamin A. Heydrick, A. B. (Harv.), Professor of English Literature, State Normal School, Millersville, Pennsylvania. Third Edition, Revised and Enlarged. New York: Hinds, Noble & Eldridge, 1904.

Several new features appear in the revised edition of this valuable little work, one of which is a list of recommended reading. In this list, not only the names of the chief writers in English and American Literature are given, but also the books or selectiones themselves which should be read in order that a fairly representative idea of the writer may be gained. The book is the fruit of the author's successful experience as a normal school teacher, and is thus eminently practical for use in the home and in literary societies.

Light Energy: Its Physics, Physiological Action, and Therapeutic Applications. By Margaret A. Cleaves, M.D., Fellow of the New York Academy of Medicine, Fellow of the American Electro-Therapeutic Association, etc., etc. With numerous illustrations in the text, and a frontispiece in colors. New York: Rebman Company, 1904.

This work is the outcome of eleven years of teaching and studying clinically the effects of light. Physics are practically considered, as they have to do with light energy and its physiological action on the various forms of life.

Strangely enough, as it might seem, the *x*-ray has not received consideration, but the author explains that sufficient good books on *x*-ray treatment have already appeared. With this we can agree, and, furthermore, the 827 pages of this volume would have had to be considerably extended. We say this, because, aside from that incidental to a certain prolixity of style, there is little subject matter that could have well been omitted.

Some of the subjects studied at length are the action of light energy upon elementary forms of life; bacteria, higher organisms, circulation, and nervous system; electric arc baths, vacuum tube discharges; radioactive substances, fluorescence, radiotherapy, pernicious effects of sunlight. There are few illustrations, confined chiefly to apparatus, cabinets, etc.

The work shows a wide range of research and considerable personal experience, in both the theoretical and the practical sides of the various questions.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Ninety-Ninth Annual Meeting, Held at [illegible], February 1 and 2, 1905.

(Special Report to the MEDICAL RECORD.)

(Continued from p. 199.)

TUESDAY, THURSDAY, FEBRUARY 2.

Election of Officers.—The annual election resulted in the choice of the following officers: *President,* Dr. Joseph D. Bryant of New York; *Vice-President,* Dr. Herman R. Ainsworth of Addison; *Secretary,* Dr. Frederick C. Curtis of Albany; *Treasurer,* Dr. Ogilvie D. Ball of Albany.

President Elect's Address.—Dr. JOSEPH D. BRYANT of New York, after being introduced to the Society by the Retiring President, Dr. Hamilton D. Wey, said that he would indeed be bereft of human sentiment if he did not express his appreciation of the manifestation of confidence shown in electing him President. He regarded himself as the servant of the entire Society, and not as a partisan of any portion of it. He said that during his incumbency of the office he would endeavor to carry into effect, so far as lay in his power, and with their aid, the unity of the profession in this State, and make it a compact body of medical men such as would gain not only the respect and confidence of the profession in this and other countries, but also the respect and confidence and heed of those who had the administration of the affairs of State and country. He asked for their counsel.

Researches on the Blood of Epileptics.—[illegible] and Dr. HORACE LO GRASSO of Sonyea presented this communication in which was emphasized the fact of a higher leucocyte count during a series of epileptic attacks.

A Case of Extensive Carcinoma of Tongue and Neck. Presenting Points of Special Interest.—Dr. WILLIAM SEAMAN BAINBRIDGE of New York City read this paper and presented the case. He said that among the widely divergent opinions regarding the etiology of cancer, it was encouraging to find a few facts so far established as to be accepted by the profession. Among these were (1) that all cancers began as a benign growth; (2) that there was, therefore, a true pre-cancerous stage, in which removal was a sure means of relief; (3) that the disease was absolutely local in the beginning, and if fully extirpated, a cure should result; (4) that extension might take place by direct infection of the surrounding tissue, but was usually through the lymphatic or blood channels; (5) that the system was poisoned by the production of toxins. In regard to treatment it had been established that arsenic paste and other caustics, besides liquid air, might cure small superficial cancers; that the Röntgen rays, Finsen light, and radium might cure selected cases of superficial cancer; that harm might result from these agencies, giving local relief but hastening systemic infection, or in some cases being followed by marked increase of the growth. The real hope of the cancer patient seemed thus far to be in operative treatment. The consensus of surgical opinion at present favored the removal as far as possible of all benign growths, especially those subjected to chronic irritation, or if malignant growth was present the removal of a margin of one-quarter to one-half inch of healthy tissue, and extirpation of lymphatic nodes and lymphatic vessels in close relation to the part affected, while in advanced cases as radical operation as was compatible with life should be employed. In some cases palliative operations lengthened life and ameliorated suffering.

Dr. Bainbridge presented a man, 49 years of age, whose mother had died of cancer of the breast at the age of 74. This patient had no specific disease, used alcohol freely, and had smoked twenty cigars daily for over twenty years, the cigar being held in the left side of the mouth, against that part of the tongue which became the seat of the disease. In May 1902, he first observed a small pimple which was treated with local applications and smoking discontinued. When smoking was resumed it returned. This was repeated a number of times. In December 1903, when Dr. Bainbridge first saw the patient, he had lost considerable flesh, and was somewhat cachectic. There was a hard, crater-like ulcer involving the left anterior quarter of the tongue, the tip being covered by a brownish fetid fur. Operation was advised, but refused. After treatment with *x*-ray, potassium iodide, tonics, etc., the patient continued to grow steadily worse, and operation offered the only possible relief from death. The growth had extended to the right half of the tongue, and there was induration of the floor of the mouth. Some cervical glands were distinctly palpable on both sides of the neck. Under chloroform and oxygen vapor anesthesia, an incision was made from the tip of the left mastoid process across the neck to that of the right, and below as far as the thyroid cartilage. Another incision was made along the anterior border of the left sternocleidomastoid muscle to within an inch of the clavicle. The ligual arteries being tied, the submaxillary and sublingual glands were removed, the salivary ducts being removed clear into the mouth. The opening of communication was closed by means of catgut sutures, care being taken to close off the apertures to Wharton's duct. Many cancerous glands were removed from the region of the tonsil on the left side to the dome of the pleura. The glands on the right side were involved from the tonsil to just below the division of the carotid artery. As far as possible connective tissue and fascia in juxtaposition to these glands were removed with them. The bisected sternocleidomastoid was sutured, and the wound, after careful hemostasis, was closed, except for a small drain at the lower part. Part of the large cauliflower mass on the tongue was removed by means of the Paquelin cautery. Whitehead's shellac was applied to the cauterized surface. The wound healed by primary union. The patient was fed *per rectum* for several days. A little more than two weeks later a second operation was performed, the left corner of the mouth being incised as far back as the edge of the masseter muscle, the tongue drawn out, and an elliptical incision made on the floor of the mouth encircling the tongue in front and on both sides, which organ was then completely removed, taking with it the geniohyoglossi and hyoglossi muscles, and one-third of the pillars of the fauces on the left side, and part of the anterior pillar of the fauces on the right side. A small flap of mucous membrane and muscle about three-quarters of an inch long, attached to the left glossoepiglottic fold, was dissected away, except where it was attached to the epiglottis and hyoid bone. This was twisted so that its left border was posterior, and its anterior extremity faced toward the left. This was sutured in place, making a bridge of tissue across the fauces in front of the epiglottis. The wound in the floor of the mouth was partially closed by chromicized catgut, and covered with Whitehead's shellac. The wound in the cheek was closed in the usual way, and shellac applied. Within three weeks the patient was discharged, and had remained apparently perfectly well, able to masticate solid food, to taste, and to talk fairly intelligently.

Dr. JOSEPH D. BRYANT of New York said he wished to emphasize the position the doctor had taken regarding the use of the *x*-ray, and the other new measures employed, except in the inoperable cases. If he had any criticism to make, he would say that the doctor should have insisted earlier upon operation. The care taken in making a thorough and complete removal of the diseased tissues deserved favorable comment. In disease of this kind complete operation only was justified, even though it might be regarded as offering but temporary relief, or at least to prevent the growth from extending to other parts of the body near at hand. Dr. Bryant had removed malignant disease from this region only to witness its rapid return when he believed it would not return; again he had removed it believing it would return, and had obtained an operative cure. Often the condition of the patient had as

much to do with his cure as the operation itself. Given two cases entirely similar so far as the morbid process was concerned, in the hands of the same surgeon who employed the same technique, one case might recover, and the patient never again be troubled with the disease; while the other case would have a hasty recurrence.

Dr. BAINBRIDGE, closing the discussion, said that he had been unable to convince the patient or his friends upon the imperative need of operation until after the *x*-ray had been tried; then he had either to give up the case or do as he did. He called attention to the place of incision on the outer side of the face; the scar now could not be seen. He also drew attention to the little bridge of tissue between the two pillars of the fauces, and said this transplantation of this bridge of tissue across the mouth was a very important part of the operation.

Prophylaxis in Pregnancy and Labor.—Dr. T. AVERY ROGERS of Plattsburg read this paper.

Special Meeting.—After adjournment of the Society a special meeting was held at the City Hall, for the purpose of taking action upon the agreement for the consolidation of this Society with the New York State Medical Association. The Society practically pledged itself to carry out what was contained in the resolution offered at the last meeting of the Medical Society of the County of New York.

FOURTH PAN-AMERICAN MEDICAL CONGRESS.

Held at Panama, January 3, 4, 5, 6 and 7, 1905.

(Special Report to the MEDICAL RECORD.)

(Continued from page 191.)

THURSDAY, JANUARY 5—THIRD DAY.

THE morning was spent informally in an excursion to Taboga island, with luncheon on board the steamer.

The afternoon scientific session was called to order at 3 o'clock in the National Theater, Dr. W. C. Gorgas in the chair.

Address on Surgery.—Dr. NICHOLAS SENN of Chicago delivered this address, taking for his subject "Coxa Vara and Differential Diagnosis Between It and Sthenic Inflammatory and Traumatic Affections of the Hip-Joint." Coxa vara, he said, was a disease of the femoral neck in adolescence, and hitherto had been rarely described in this country. Mueller was the first, in 1888, to subject it to earnest clinical study, and to prove that it was a disease entirely different from any other hitherto described. Hofmeister and Kocher, six years later, contributed to the study. The French seemed to have neglected the disease. Kocher thought that it was an occupation disease, as he found it chiefly in laboring men. Genuine coxa vara was characterized by a non-inflammatory softening of the neck of the femur. It was a self-limited disease, confined to the femoral neck, and characterized by anatomical changes. Senn reported two typical cases in young men, and a third in a man 42 years old. This last case had all the classical signs, and the *x*-ray showed that there was no fracture of the femur, as had been suspected before the case came into his hands. There had been the usual pains in the hip-j[illegible] referred at times to the knee, coming on in paroxysms which would last for two weeks, followed by pain[illegible] vals of several days. There was no tenderness nor impairment of joint motion. The pain was not aggravate[illegible] standing or walking. After two occasions in which the patient slipped and increased the pain, he noticed that the leg was shorter. When seen by Senn he walked with a decided limp, and complained only of muscular w[illegible] Any infection could be excluded, and there was certainly not a complete fracture. The spontaneous recovery, as well as the degree of bending downward of the neck of the femur in its entire length, and the complete absence of neoplastic inflammatory products excluded absolutely the possibility of arthritis or senile coxitis. Tuberculosis could also be excluded.

Very little was known, the speaker said, concerning the true nature of coxa vara. The softening of the neck of the femur was the most important element. Some claimed that this was caused by a localized osteomalacia; others regarded it as the late form of local rachitis. The primary bone affection was of a self-limited character, as spontaneous recovery was the rule. The active condition might terminate in a few months, or it might be protracted for years. The first symptom was pain in the hip-joint; the function of the joint was not always seriously impaired. Ordinarily patients were well enough to be about, although quite lame. There was no elevation of temperature or other constitutional disturbance, nor was there any tenderness about the joint; patients usually thought they were suffering from rheumatism; the general health was not affected by the disease, but the limb was shortened both apparently and really. Trauma, tuberculosis, and inflammatory conditions must be excluded. Life itself was never threatened, as the disease was self-limited, and sooner or later ended in spontaneous recovery. General treatment was unimportant if not useless. Local treatment must tend to relieve pain, and to limit the bending of the neck of the femur; both of these results were secured by absolute rest in bed combined with extension. Operative treatment should be postponed as long as possible.

The Address in Hygiene.—Dr. CARLOS J. FINLAY, Chief Sanitary Officer for Cuba, had prepared this address, which was read by Dr. Martinez of Havana, on the "Sanitary Conditions in Cuba Since the Proclamation of the Republic." He divided the subject into three separate parts: (1) Special sanitation against yellow fever; (2) special sanitation against other infectious disease; (3) general sanitation for the preservation of public health.

Special Sanitation Against Yellow Fever.—Havana had had a bad reputation as the center for yellow fever, and therefore its sanitary condition since the proclamation of independence deserved to be considered. In Havana in February, 1901, was made the first proclamation of a doctrine which had been experimentally demonstrated with no room for a reasonable doubt as to its correctness. The doctrine of the mosquito propagation of yellow fever had since been abundantly proved in Vera Cruz, in Sao Paolo, and in Rio Janeiro. Many did not yet acknowledge that *Stegomyia fasciata* was the only agent through which the disease would be propagated, but the author claimed that this was the only method, and that to keep yellow fever patients from being bitten was the only means of suppressing the disease. Havana had had thirty-six months of uninterrupted immunity, during which not a single case of yellow fever had originated in the city. No other precautions were observed than to prevent the bite of the mosquito. Colonel W. C. Gorgas, Chief Sanitary Officer of Havana until May 20, 1902, first drove the infection from the city, and since his régime and up to the present date, December, 1904, notwithstanding the importation of twenty-two cases from foreign ports, not a single case of yellow fever had occurred in Havana, nor until two months ago in any other part of Cuban territory. On October 20, 1904, an American, who had arrived at Santiago on September 27, was reported as taken ill on the 17th and first seen on the 20th of October. The diagnosis was confirmed. The source of the infection could not be traced to the neighborhood. It was assumed, therefore, that it might have been caused by some infected mosquito from one or other of the vessels held in quarantine in Santiago Bay. Some wind may have blown the mosquito ashore. A careful inspection was made; the houses were fumigated, and breeding places as far as possible destroyed, and all non-immunes were quarantined. Thirteen or fourteen days after this invasion another non-immune American was taken ill, and reported as a suspect of yellow fever. He was removed, and the previous measures of disinfection repeated. The diagnosis was confirmed. No other case occurred.

Special Sanitation Against Other Infectious Disease.—The acute quarantinable diseases with which the Island of

Cuba was particularly concerned were yellow fever, smallpox, cholera, and plague. None of these diseases, except those cases mentioned, and one case of smallpox, due to an accidental contagion which did not spread, had occurred. Physicians in Cuba were obliged to give notice of forty-one diseases, but many of these were listed for the purpose of avoiding errors in diagnosis, or to obtain information which might throw light on the uncertain cause of a disease responsible for a large proportion of infantile mortality. Against smallpox they trusted to isolation and vaccination. Against diphtheria, isolation and antidiphtheritic serum prepared in Havana had given excellent results. Cases of infectious diseases were isolated at home or in some special hospital, like Las Animas in Havana. At Santiago, the establishment of a similar hospital had been authorized.

General Sanitation for the Preservation of Public Health.—The Cuban Government had maintained the Sanitary Department established by the United States, and brought to its aid all that science could furnish, but outside of Havana, no permanent sanitary improvements had been achieved, although plans were well devised in a satisfactory way. The country was as yet too poor to do very much, but the mortality over the whole island had been low compared with even favored regions outside the tropics.

Dr. PURNELL, Acting Assistant Surgeon of the Marine Hospital Service at New Orleans, congratulated Cuba and the United States on the work accomplished. Although he accepted the mosquito theory, he did not do so absolutely. He thought there were cases not explained by this theory, and that measures of prevention besides the attack on the mosquito should be adopted. The great epidemic in Memphis in 1879 occurred after a severe cold winter, but not until the 9th of July. If the mosquitos alone were the cause, it ought to have appeared in April. He had known in 1897 of several epidemics in small towns in Mississippi. In one 299 cases occurred among 355 whites, which could hardly be explained by the mosquito alone; but the epidemic was suppressed, although the mosquito was not attacked. Why was it that in the Island of St. Thomas the disease was so deadly, and yet ordinary cleanliness had driven the fever away? In New Orleans, yellow fever was nearly obliterated during the control of the Marine Hospital Service by cleanliness, but it recurred. He criticised the statement that the mosquito biting the Santiago patient was blown from the sea. In Jackson, Mississippi, he had known of an outbreak among men working in buildings which ten years previously had been infected by yellow fever. It certainly was the tradition of the Mississippi valley that fomites had something to do with the spread of yellow fever.

Dr. R. H. CARTER, Chief Quarantine Officer of the Isthmian Canal Zone, said he was sure that yellow fever was borne by the bite of a mosquito from sick to well and thus only. He, himself, had helped to stamp out epidemics, by methods not necessarily directed against the mosquito, such as isolation, fumigation, etc., but he knew that their efficacy had destroyed the mosquito incidentally. Many former methods were still in use, and applied in the same way, but they were now directed against the mosquito. Sulphur, for instance, was a good insecticide, but it was not much of a disinfectant. Saint Thomas was no longer a port of call, so that there was no immigration or emigration to or from the Island, no change of population, no new blood, and yellow fever could no longer be propagated when the infected stegomyias had died out. In New Orleans, to be sure, the city was well cleaned, but at the same time commerce was stopped. He remembered in June, 1900, speaking to Major Reed, and advocating Finlay's mosquito theory. Reed then quoted Sternberg that the theory was admitted, but not established. It had never been proved that fomites played any part in the disease. A negative argument was easy, but something more was needed for a demonstration. For instance, Havana was cleaned clean. For ten years before that the death rate per 1,000 had averaged 210.6; from March, 1898, to March, 1899, there were 121 deaths. The next year, after Havana had been cleaned, yellow fever spread and there were 315 deaths—the worst epidemic in eighteen years. In this case, cleaning had not helped; but when the fight was made only against the mosquito, and isolation was practised, the fever stopped without any cleaning.

Dr. STERN of Jamaica and Panama agreed with Dr. Purnell in not accepting the mosquito theory as the only cause.

Dr. COOK of Panama could not accept the mosquito theory alone, because epidemics ceased spontaneously, and yet when there are plenty of mosquitos, sometimes, no outbreaks occurred. Also he had seen single cases from which no others in the neighborhood were infected.

Dr. CHASSAIGNAC of New Orleans accepted the mosquito theory as irrefutable. He believed the Havana experiments to be positive, and there was no other means of conveying the disease; but we should sympathize with those who still held to other beliefs, and not insist upon acting too radically.

Dr. HUGHES of St. Louis had had experience with yellow fever in his early practice. He now accepted the definiteness of the results of the mosquito theory, but was not convinced that this insect was the only means of propagation. He thought flies might transmit the disease.

Dr. CARTER, in responding to the question of his opinion regarding fomites, said that there could be only two ways in which they could convey the infection, one was by direct contact as when one opened a trunk, the other by environment. If either means were admitted, infection should take place anywhere. Yet for twenty-one years, no baggage from Cuba or Vera Cruz had been kept out of New York. In Spain, for twenty-eight years, no baggage had been protected. He estimated that probably 600,000 persons with 1,000,000 pieces of baggage had traveled from infected ports during that time. The United States sent many soldiers from Cuba back to Spain, where they met no detention, and yet from all of this, there was not one single case of infection. Havana and Vera Cruz are in close touch, and yet for four years, with no attempt to sterilize baggage, Havana had escaped infection.

Dr. W. C. GORGAS acknowledged that at one time he thought fomites to be the only means of transmission of yellow fever. He then differed thoroughly from Dr. Finlay, but Major Reed had finally argued him around, and the proof offered in Havana was enough to convince him thoroughly. Another instance of the harmlessness of baggage was seen in Havana, where people from the suburbs were constantly moving back and forth, but never brought infection with them.

Dr. LEWIS BALCH said, in answer to a question as to the best means of fumigation, that he now relied upon 2 lbs. of pyrethrum to 1,000 cubic feet, with two hours' exposure; this gave absolute results in killing mosquitos. He had just disinfected a room where the mosquitos were picked up dead on the floor. It was customary to burn them whether dead or not.

Dr. THOMAS, resident physician Mississippi Valley Quarantine Station, Louisiana, said that he had used pyrethrum but found it valueless. Sulphur was now employed exclusively in Louisiana. He asked how, if Santos, in Brazil, had been freed from yellow fever by cleaning alone, while the mosquito was not attacked, its present immunity could be explained on the mosquito theory. In the Mississippi river stations they were compelled to accept other means of explanation besides that of the mosquito. Many people in the State still clung to that belief, and it would not be right to ignore their feelings.

Dr. ECHEVERRIA of Costa Rica upheld the mosquito theory, and said that yellow fever had never been known to occur where *Stegomyia* could not be found.

Dr. MARTINEZ, in closing, called attention to the fact that the old reviews and description of methods of disinfection did not mention mosquitos at all, but they may have been

killed without any attention being paid to them. To explain isolated outbreaks, it was assumed that children preserved the organism in the blood (as they did that of malaria) and thus offered a source of supply to the mosquito. The study of the development of the parasite in the mosquito showed that an intermediate host was necessary, just as it was in the case of the tapeworm. He said that one reason Santos was not so infected, was that even if the town had not been cleaned, Rio had; and that there was therefore less transmission of the disease from one city to another. It must be remembered that the U. S. A. Commission had studied the question of fomites very thoroughly. In its report, one instance was given in which the blankets, clothing, and bedding of patients ill or dead from yellow fever had been stored in a room and used by two sets of non-immune fresh arrivals in Cuba, any yet no single instance of infection from this clothing had occurred.

Dr. Charles Chassaignac of New Orleans offered a resolution that, "owing to the suffering and to the serious danger to health and life for which the mosquito is known to be chiefly, if not solely, responsible, it is the imperative duty of all communities and governments to use all the means in their power for the destruction and gradual annihilation of the pestivorous insect in question."

The resolution was adopted.

The evening was spent at a ball given the delegate officials, and townspeople, at the International Club.

FRIDAY, JANUARY 6—FOURTH DAY

The morning was spent, by the courtesy of the Panama Railroad and Isthmian Canal Commission, at Culebra and Empire in looking at the work and progress under the Americans. At 10 o'clock word was received that the *Athos* had just arrived. Those who were already at Culebra were entertained at luncheon by Dr. Bell of the Navy and Captain McKinney of the U. S. Marine Corps, stationed at Empire. At 12 o'clock a special train bearing the *Athos* delegates arrived at Culebra, where they remained, while those who had already seen the canal returned to Panama.

The scientific session was called to order at 8:45 P. M., Dr. Icaza in the chair. He said it was a freak of fate that the largest meeting should be called after the Congress itself had virtually adjourned, but he had to seize the opportunity of calling for responses from the various delegates present. These responses were given by Martinez of Cuba, W. W. Keen of the United States, José Ramos of Mexico, Azurdia of Guatemala, Biffi of Peru, Cordova of Honduras, Echeverria of Costa Rica.

Care and Cure of Epilepsy.—Dr. Hughes of St. Louis read this paper. He claimed that epilepsy could now in many cases be listed with the curable diseases. He reported ten cases under observation for twenty-five years in which there had been no recurrence. In treating epilepsy, he always demanded an agreement that the patient should be under control at least two years, during which time he would treat every function of the individual so as to keep his general health in the best possible condition. Of course, institutional treatment was better in most cases than private treatment.

Dr. A. E. McDonald of New York made a report for the delayed passengers on the *Athos*. He said that when they realized that it would be impossible to reach Panama on time, the delegates and members decided to hold meetings on board. This was done; papers were read and discussions carried on, of which records were kept, and he moved that such papers and discussions be allowed to be entered on the minutes of the Congress as part of the regular transactions. This resolution was adopted by a vote of 23 to 7.

Permeability of Filters to the Protozoa of the Waters Used in the City of Lima.—Dr. Hugo Biffi of Lima read a paper on this subject, detailing the results of various experiments. The idea of these experiments was to see what filters were serviceable not only in providing good drinking water to those using them, but in securing sterile water for laboratory purposes. They found that some amebas and flagellate bacilli passed through all filters. Most filters suffered from prolonged use. The Berkefeld and Grandjaen filters allowed the passage of cilia of 30 to 40 microns and everything smaller. They considered this the best filter.

Suppression of Plague.—Dr. José Ramos of Mexico explained the methods by which the Mexican Government had been able to suppress the outbreak of plague at Mazatlán in 1900. They did not hesitate to resort to the most energetic and radical measures. Complete isolation of plague patients was insisted on. Disinfection was thoroughly carried out; destruction of rats was attempted on a very large scale, and even houses were destroyed by fire to reach results. By these measures the plague at Mazatlán was entirely overcome so that it did not spread out of the original infected area. They had established two zones of quarantine, so that no one could leave the city without two thorough examinations. They had found the use of antiplague serum very efficacious in suspected cases.

SATURDAY, JANUARY 7—FIFTH DAY.

A meeting was called to order at 8:45 A. M., Dr. Icaza presiding.

Trachoma in Mexico.—Dr. José Ramos of Mexico read this paper. The disease was gradually spreading in the Republic, and there were certain well recognized areas where it was more frequently found, but there was no doubt that the elevation at which most of the people live had a good influence on the disease, and that it was rather more benign there than in other parts of the world. However, as the disease was spreading, he thought such methods as had been found useful in Germany ought to be adopted in Mexico, viz., the institution of courses of lectures for general practitioners throughout the country on the diagnosis and treatment of trachoma.

Dr. Calvo then read by title all of the papers presented, the authors of which were absent or had had no time to read their communications.

Dr. Obarrio reported the action of the secretary and treasurer of the local committee.

Dr. Izaca then announced the Congress adjourned.

Dr. Ramon Guiteras then called a meeting of the Executive Committee, at which the following resolutions, proposed by Guatemala and seconded by Peru, were carried:

(1) That the next Pan-American Medical Congress arrange (*a*) for an International American Pharmacopeia; (*b*) for an International Code of Sanitation; (*c*) for an International Code on Temperance, and (*d*) as a sequel to the above, for the establishment of sanatoria for the treatment of alcoholism; (*e*) for the formation of lectureships on Medicine, in the required Studies of Jurisprudence.

(2) That there be formed at the next Congress a Section on Tropical Diseases.

(3) That there be created Red Cross Branches, both Civil and Military.

(4) Finally it was resolved that encouragement be given to those engaged in the campaign against tuberculosis.

It was decided to hold the next meeting in the City of Guatemala, Guatemala, in 1908.

THE NEW YORK STATE MEDICAL ASSOCIATION

NEW YORK COUNTY.

Stated Meeting, January 16, 1905.

The President, Dr. Francis J. Quinlan, in the Chair.

Health of the Nation.—Dr. Walter Wyman, Surgeon General of the United States Public Health and Marine Hospital Service, read this paper. He said that the topic that had been assigned him was a rather broad one, and in dealing with it he would limit himself to an expression of general ideas and principles rather than take up the time of the Association by going into the details of sanitary work, and giving statistics of disease which could be found in the

medical journals, and public health reports. It was a somewhat trite idea, but one whose significance was of great present import, that the nations of the earth to-day were more nearly related than ever before in the world's history. All the world had become one neighborhood, so far as related to distances. In no manner had this been better shown than in the warfare against contagious disease. Only a few years ago a violent epidemic of yellow fever in Cuba would excite no more than passing notice, while to-day the news of two cases in Santiago was immediately wired throughout the United States and foreign countries. A few cases of bubonic plague in the Orient, which a few years ago would have received no attention, were instantly reported, and published throughout the United States, and one case of cholera on a ship in the Mediterranean, was likewise telegraphed to the principal cities of the world. International congresses, conferences, and conventions were frequently bringing the nations together as one family, in the struggle against these foes of mankind. We heard much of international peace conferences, and arbitration treaties. Was it too much to expect, as a corollary or parallel movement, the cooperation of nations to prevent and suppress communicable disease? International sanitation might well be considered as adjunctive to the movement for universal peace. If, as Tolstoi said, the only substitute for war was religion, international sanitation would be a powerful weapon in the hands of religion. It surely would furnish a plane upon which nations might meet. It suggested a common enemy, disease, against which all might combine without fear of international complications, and which furnished a more worthy object than war for the expenditure of energy and money.

Health of the State.—Dr. Daniel Lewis, Commissioner of Health, State of New York, first called attention to the fact that the old State Board of Health, which was established about twenty-five years ago, and consisted of nine members, was abolished four years ago, and in its place was established the State Department of Health, with a single head, the Commissioner of Health, upon whom devolved all the duties which formerly belonged to the State Board of Health. Dr. Lewis then described in detail, the work of his Department, and the various State institutions that were under its jurisdiction. This included

manufactured, and supplied gratis to the State health

where blood, sputum, etc. were examined for the State

was chiefly confined to the examination of drugs and illuminating oil. Twenty years ago the duties of the chemist of the State Board of Health were far more important

State. Dr. Lewis said there were about 1,400 health officers throughout the State, and he regarded their establishment upon a permanent, substantial basis as one of the most important things accomplished by the new Department. In addition to the sanitary inspection done by the local health officers, there were consulting engineers who examined and approved or disapproved of the sewerage systems throughout the State. No village could instil a sewerage system until the plans had been approved by the engineers of the State Department of Health: not even the bonds for the payment of such improvements could be disposed of until that formality had been complied with. In speaking of a pure water supply, Dr. Lewis referred to a law that had been passed in 1902, making it a misdemeanor to pollute any of the brooks or streams or water-beds of the State. This law, the speaker said, would in time, provide pure water for the people of the State. It was encouraging to note that the public at large was beginning to take more interest in this subject.

Health of the City.—Dr. Thomas Darlington, Commissioner of Health, City of New York, said that the work of the Board of Health was so extensive, embracing, as it did, forty-four separate and distinct lines, that he would confine his remarks principally to a consideration of the death rate and the general health of the city. The health of the City of New York had been far from satisfactory during the past year. The number of deaths reported during the year 1904 was 77,985, an increase of 10,121 as compared with the previous year, and of 9,403 as compared with the average for the preceding five years. The year 1903 was remarkable for the lowest death-rate on record for the city, namely, 18.18 per thousand, and for the remarkable absence of a severe epidemic in any of the communicable diseases, an experience shared by all the principal cities of the world. On the other hand, the year 1904 was remarkable for the directly opposite condition of affairs. This increase in the number of deaths was due, first, to the increase in population. The speaker thought there were at least 200,000 or 300,000 more people in the City of New York than were accounted for in the increase in the census returns of the year 1900. The principal increase in the deaths had been due to the acute respiratory diseases, pneumonia, bronchopneumonia, and acute bronchitis. The total number of deaths from these causes was 14,518, as against 11,540 in 1903, showing an increase of 2,978, or nearly one-third of the total increased number of deaths. The prevalent influenza during the first quarter of the year, the severe epidemic of measles, and the unusual severity of the weather, accounted largely for the increased number of cases. During the second quarter of the year, the severest epidemic of cerebrospinal meningitis for thirty-two years served to increase the deaths 1,200 over the previous year, and there was an increase of 200 deaths from simple spinal meningitis (which were probably cases of cerebrospinal meningitis), making the increase from this source probably 1,400 deaths. The next factor in severity as a cause, was the increase in diarrheal diseases, especially among children under two years of age. The exact reason for this outbreak had not yet been ascertained. There were more inspectors on the Summer Corps, and more nurses than ever before, and they did as good work, if not better, than ever before. The increase in deaths from diarrhea among children under two years of age was 1,196 or one-ninth of the whole death rate. The increase in deaths from pulmonary tuberculosis was 475. From nephritis there was an increase of 568 cases, and from cardiac diseases 226 cases. From both of these causes there had been a steady increase in the deaths since 1868. Possibly, a slight proportion of this was due to better diagnosis, but undoubtedly the greater portion of it could be attributed to the pace at which the average New Yorker was living, taking too much food, too little proper exercise, too many stimulants, and too much worry and fret. The number of cases of typhoid fever were 300 fewer than usual; fully 25 per cent. of the cases, if not more, acquired the disease outside of the city, while the rest were accounted for by the water, milk, the use of green vegetables and oysters. The number of cases of diphtheria were about 500 less, and the mortality rate had decreased one per cent. of the whole death rate. Dr. Darlington said that while the general mortality of New York City, and of the United States, as a whole, had steadily decreased in the last thirty years, owing to improved sanitary conditions, and the increase in our knowledge as to the cause and nature of diseases, yet in the case of several diseases the mortality had not fallen, but had actually increased. Of these, the most notable and important examples were pneumonia and cancer. The death rate from pneumonia had risen steadily from 1.95 per thousand in 1870, to 2.89 per thousand in 1903. In 1870 deaths from this cause constituted only about 7 per cent. of the total death rate; in 1903 it constituted 15 per cent., having more than doubled, and in 1904 it constituted 19.5

per cent., and this in spite of the fact that the disease in some respects had been quite thoroughly studied. It had been known for some years that lobar pneumonia was an infection usually caused by the pneumococcus; the predisposition to it was usually due to exposure to sudden changes of temperature, or cold, or to over-exertion, exhaustion, alcoholism, etc. It was especially fatal in water-side and low, damp districts, and was very prevalent among negroes and persons of Irish descent, and in those whose occupations kept them out of doors, or subjected them to sudden changes of temperature: as a rule, it was feebly communicable, but might even become epidemic. The problem of the prevention of pneumonia, Dr. Darlington said, had become the most urgent one in preventive medicine. At the request of the Board of Health, the Board of Estimate and Apportionment had appropriated a sum of money for the special investigation of the acute respiratory diseases, and the Board of Health had appointed a commission to conduct the inquiry. The investigation of this commission would proceed along two main lines, clinical and bacteriological. For the attainment of a solution of this all-important problem, the assistance of every physician in New York City and elsewhere, was most earnestly and confidently solicited.

Health of the Port.—Dr. Alvah H. Doty, Health Officer of the Port of New York, was unable to be present at the meeting, and his paper was read by Dr. Charles E. Denison. The writer stated that the health of the port of New York could best be considered in connection with a description of the diseases which were dealt with at the New York Quarantine Station, and the methods employed to prevent their entrance into this country. It might be truthfully said that in the past no disease which had visited the United States had caused such consternation, and so great a loss of life, or had been responsible for such stringent rules and regulations on the part of health authorities, as yellow fever. Not only just, but unjust means had been employed to prevent its extension. They had been carried to such an extent during the presence of epidemics in the South, that the commerce of that section had been at times practically paralyzed. The enforcement of drastic measures was largely due to the belief that yellow fever was transmitted by personal contact with the patient, by discharges, by the clothing and effects of the sick, cargoes of vessels, merchandise, etc. Even iron rails had been regarded as a medium of infection, and had been subjected to disinfection. To-day, Dr. Doty said, we knew that such regulations were unnecessary, as it had been conclusively proven by the most careful and thorough investigation that yellow fever was conveyed from one person to another by the mosquito. While there were some who still believed that there might be other means of transmitting the disease, there was at present no proof of this, and for practical purposes it might be regarded as safe to assume that the mosquito was the only means by which yellow fever was conveyed. The importance of this knowledge could not be over-estimated, inasmuch as it placed in our hands means by which formidable and dangerous epidemics of yellow fever could be prevented. These consisted principally in confining the yellow fever patient in an apartment completely protected by screens to prevent the entrance or exit of mosquitos. This measure of protection was easily carried out, and in order to be eminently successful, it required that cases of yellow fever should be detected very early. Aside from the use of agents such as sulphur dioxide in apartments to destroy the stegomyia fasciata, disinfection was now regarded as unnecessary. Exhaustive experiments which were made at the New York Quarantine Station had conclusively proven that the mosquito could not live in closed trunks, bags, and other receptacles for a longer period than twenty-four or thirty hours; therefore, the disinfection of baggage that had been in transit more than two days, would seem to be uncalled for. Another factor which had recently made considerable change in quarantine methods, particularly at the port of New York, was the means employed to prevent the entrance of bubonic plague into this country. Formerly, we had very meagre knowledge of the character and habits of this disease. In order to detect its presence, it was necessary to bear in mind that it might appear either in the "bubonic" form, which was associated with enlargement of the superficial glands, particularly those in the inguinal and axillary regions, or in the "pulmonary" form, which principally affected the lungs. Aside from the transmission of the disease by personal contagion, it was necessary that proper consideration be given to the rat, which had been regarded as a common means of conveying the disease from one person to another. Although there was no doubt as to the truth of this, there was also no doubt that the importance of the rat in the transmission of bubonic plague had been over-estimated. In addition to vermin, we had yet to consider the probability of the disease being conveyed by insects. The pulmonary form, which was common, and very fatal in India, was not usually seen on ship-board. In vessels arriving from cholera ports, great care was taken to detect that disease in its various manifestations. Fortunately, vessels coming from cholera and plague-infected ports as a rule carried no passengers. Typhus fever and smallpox, which completed the list of the five diseases that were specially subject to quarantine regulation, were also carefully watched for, particularly if there was reason to believe that they existed at the ports of departure. In order to insure the detection of infectious diseases during the stage of invasion, all persons arriving at this port on foreign vessels who had fever, as indicated by the thermometer, and which could not be satisfactorily accounted for, were subject to removal to Swinburne Island for observation. In this manner, many cases of infectious disease had been prevented from reaching the city. Dr. Doty said he felt confident that the clothing worn by well persons, textile fabrics (other than those used about the sick), merchandise, cargoes of vessels, etc., rarely acted as a medium of infection. The inspection of passengers and crews at the New York Quarantine Station was of the most rigid character. Neither the bill of health, the statement of the ship's captain or surgeon, nor of anyone else, was taken in lieu of a careful personal examination when called for by the regulations of the Department. In cases where disinfection was necessary, steam at a temperature of 230° F., with an exposure of fifteen minutes, was used for the treatment of clothing, bedding and other textile fabrics, inasmuch as steam was the only agent that could be depended upon to thoroughly penetrate the material referred to. When furs, silks, satins, and other delicate fabrics, and also leather goods, etc., which would be destroyed or injured by steam, were to be disinfected, formaldehyde gas was used. In those cases, every article was carefully hung up and spread out, in order that all surfaces should be exposed to the gas. Formaldehyde was also used in the disinfection of saloon apartments which contained fine fabrics, gilding, etc. Hot water and soap, sulphur dioxide, bichloride of mercury and carbolic acid were variously used in the cleansing and disinfection of the ship's forecastle and other apartments after the removal of merchandise, etc. The thorough use of soap and water by scrubbing, followed by the generation of sulphur dioxide or formaldehyde gas in a closed apartment were as a rule, all that was required to insure safety against infection. In transatlantic mail steamships the deposition of the captain and surgeon that the saloon passengers and crew of the vessel were well, was under ordinary conditions, and where no epidemic of infectious disease was prevalent at the port of departure, accepted in lieu of an examination. Under no conditions, however, were the steerage passengers exempted from examination.

Dr. Stephen Smith said that forty years ago there was no health organization of an administrative kind in the United States that was accomplishing any good, neither were there any health laws of a systematized kind. So far as he knew, the organization of the New York Department

of Health in 1866 was the first practical step taken towards the enactment of health laws that ended with the complete unification of the sanitary administration of the entire country, as it existed to-day.

Dr. S. A. KNOPF said that many persons died of tuberculosis, not because it was an incurable disease, but because there was no adequate provision made for the care of these patients. He referred to the tenement house evil, and said that an important step to remedy it had recently been inaugurated by Mr. Henry Phipps in donating one million dollars for the erection of model tenements. In the prevention of pneumonia, the study of the individual, his habits, occupation, etc., was an important factor, also the proper ventilation of public buildings, theaters, schoolrooms, and even of the New York Academy of Medicine itself.

Dr. CHARLES S. BENEDICT described the work of the experimental tuberculosis sanatorium that was being conducted by the New York Board of Health on North Brother Island, and said that excellent results had been achieved there thus far.

Dr. Wyman, in closing, paid a high tribute to the part played by Dr. Stephen Smith as an advocate of sanitary reform. The great value of Dr. Smith's services were highly appreciated, and among the health officials at Washington he had long been regarded as one of the staunchest friends of the public health.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 26, 1905.

DR. A. PALMER DUDLEY IN THE CHAIR.

Election of Officers.—For *Chairman,* Dr. Charles F. Adams; for *Secretary,* Dr. Arnold Sturmdorf.

Presentation of Bullet Wound of Spleen, and Report of Case.—Dr. A. PALMER DUDLEY reported the case of a man who had received three bullet wounds, one through the shoulder, which shattered the acromial process, one through the thigh, and the other through the spleen. The spleen was presented for inspection. The post mortem was performed by Dr. Shultz at Bellevue Hospital. The patient had been shot in Little Italy. The bullet through the shoulder had lodged behind the scapula. The one through the thigh came out, although the Coroner thought the scar showed a point of entrance rather than exit. The third bullet had entered through the side, below the diaphragm, and had passed through the spleen. It had evidently gone behind the kidney and carromed off and gone twice through the diaphragm, and through the lung, and the man died of compression of the lung. His chest was filled with blood. A double hole was made by this bullet through the diaphragm, the holes being about one inch apart. There was no hole through the thoracic wall above the diaphragm. The bullet could not be found. The patient died from a gradual leakage from a small artery. It took two days for enough blood to leak to affect the heart. The curious thing regarding this accident was the fact that there was no opening above the diaphragm.

The After-Treatment of Abdominal Section.—Dr. DANIEL H. CRAIG of Boston addressed the Section on this subject, speaking only of the actual details of the after treatment of abdominal section with eserine. He thought it would be a very wise thing if more attention was paid to these little details, apparently trifling in their nature, yet a thorough familiarity with them would show improvement in results obtained. He said there was no absolute routine to be followed in giving eserine salicylate, but one should, whenever possible, follow the individual requirements of the case. In order to regulate bowel activity he administered hypodermically 1-60 of a grain of eserine salicylate, and repeated this dose in some instances, and he got very good results. If there was given a history of chronic constipation the dose should be 1-30 of a grain; if there was much atony then 1-24 or even 1-20 of a grain might be given. It was his practice to give hypodermically 1-40 of a grain of eserine salicylate, and, if the dose was inadequate, to repeat it. But, as a matter of fact, he had been obliged to give a second dose of eserine only twice. Eserine salicylate should *never* be given except with atropine sulphate; atropine antagonized the disagreeable effects of eserine, and should never be omitted. The time to give atropine was of the utmost importance; it should be administered hypodermically prior to giving the anesthetic. Or 1-100 of a grain should be given by the mouth one hour before the anesthetic. If there was no time to choose, the eserine should be given while the patient was being put under the anesthetic. There were really no contraindications unless there were strong adhesions, in the liberation of which the muscular tunic of the bowel might be injured. Again, in intestinal resection or anastomosis there should be rest. In pelvic surgery of simple kinds, where there were no adhesions, eserine should be given two to five minutes after the initial incision. Eserine should not be given before the operation was begun. He said there was another class of cases in which eserine should be withheld, viz., when septic material was left behind; then nothing should be given which would prevent walling off by adhesions taking place. He said that the necessity of administering eserine in every case had been questioned, and that Dr. Stone, in a recent paper, had cited him as using it in every case. It should be remembered that the abdominal cavity was never opened without interfering more or less with the normal peristaltic action. When they possessed a remedy as harmless as eserine he believed they were perfectly justified in administering it. Dr. Craig then considered the exact method of the action of eserine in combating postoperative intestinal paresis, and referred the members of the Section to his previous papers on this subject. He said that some advocated the giving of eserine at a later period than he, but for what reason he did not know. So far there had been no untoward effects reported by anyone, but there had been reported many instances of an early restoration of intestinal peristalsis, and a marked amelioration of the postoperative vomiting. The action of this agent in increasing the pharyngeal secretion did away with the postoperative dryness of the throat which resulted from the giving of atropine. Dr. Adams had reported a feeling of muscular depression and weakness after eserine; if atropine had been used no such effect would have been noted. If eserine be used in the after-treatment of abdominal section, somewhat the same effect would be had as after the administration of saline cathartics. The day on which the bowels should move was to him a matter of no importance. A semi-solid diet was permitted on the third day, and a full diet on the fourth. But since he had come to a knowledge of the proper dose of eserine, in no case had the bowels failed to move within twelve or twenty-four hours. With regard to eserine itself, only the salicylate should be used. The sulphate was deliquescent and unreliable. The other preparations of physostigma should not be used either, because they contained the other alkaloids of calabar bean. Eserine being the vegetable active principle, it was probable that failures might result at times through some idiosyncrasy or peculiarity in the drug itself. The drug should be obtained directly from the makers, and in small tubes. Dr. Craig closed his remarks by speaking of the absolute comfort and feeling of wellbeing which followed the administration of eserine; the pain in the abdomen was not the rule. In any case in which there was pain, and morphine was required, it could be given with the greatest freedom when eserine had been administered.

Dr. EGBERT H. GRANDIN said that one month ago (see page 116) he had outlined the methods that had given him the best results in all his abdominal work, and he then stated that he had not used eserine, although he had been familiar with its use after reading Dr. Craig's previous papers. He had never used it because he had not found occasion to do so. What he had always used was a fair sized

dose of colomel a few hours before the operation in every case in which he expected or suspected the possibility of infection. He said he wished to thank Dr. Craig for coming from Boston and telling what he did in these cases. Dr. Grandin said he had been taught that through the proper use of eserine we should probably not be required to resort to laxatives after operation, and that he believed it to be a most valuable point. All knew how difficult it was to introduce into an irritable stomach calomel or salts. If it was found that the judicious use of eserine made it unnecessary to give calomel or sales for thirty-six or forty-eight hours after the operation, he thought that Dr. Craig was entitled to the gratitude of both surgeon and patient. Still, whenever he was called upon to operate where he thought that septic material might soil the peritoneal cavity, he would continue to use calomel. As a routine measure, and as a result of hearing Dr. Craig's remarks, he said he would start right in and use eserine according to the directions stated.

Dr. Hermann J. Boldt said that he had resorted to the use of eserine only two years ago as a remedy against the possibility of intestinal paresis, but he had not given it as Dr. Craig advocated. He began using it in all instances of meteorism in doses of 1-60 of a grain when there were no evidences of an inflammatory process. He soon changed the dose to 1-40 and then to 1-20 of a grain. In some instances the dose was repeated. As a result, in nearly all cases when the distension was not of inflammatory origin, he had been perfectly satisfied with its action. He said he would now use this agent as Dr. Craig advocated. With regards to diet, so soon as vomiting had ceased he gave a full diet, and did not restrain his patients at all, giving them liberty to move about as they felt like it. The patients were out of bed on the fifth or sixth day, and he had never regretted it unless the condition of the abdominal wound contraindicated it. It should be borne in mind that meteorism that was inflammatory or of septic origin would not be affected by any medicament.

Dr. William S. Stone said that, granting that the septic cases were not affected by the administration of eserine, it was the general experience in all cases that, if not septic, the patients got well whether eserine was given or not; so while they praised the results of Dr. Craig's work, misstatements and misrepresentations should be guarded against, and it should be borne in mind that the method Dr. Craig was offering was not a life-saving one. Cases of intestinal paresis ordinarily got well.

Dr. Philander Harris said that the administration of eserine did more than merely give comfort to the patient; by lessening the tympany it removed a factor in the production of, or intensity of, sepsis. He considered the suggestions made by Dr. Craig as being most valuable, although he did not think that he would adopt its use, preferring the treatment outlined by him at the last meeting of the section.

Dr. John Douglas said that during the last two months eserine had been used at St. Luke's Hospital, but mostly in an experimental way. Unquestionably the after-effects (50 per cent. of these were gynecological cases) showed less tympany, and the patients appeared to be in better condition. This agent had also been used on the medical side in typhoid fever.

Dr. Daniel H. Craig closed the discussion by stating that his remarks were simply elementary, and could not be else, because the subject was such a big one. If anyone intended to try it, he advised them first to study the method carefully, and read over his previous papers on the subject. It was with some trepidation that he arose to differ with Dr. Grandin regarding the employment of calomel in either large or moderate sized doses. If there was an agent which could be given after the operation to procure rest to the intestines when it was indicated, it would be far better than giving something before the operation. He said that cases of paresis were sometimes apparent, and sometimes real, and often cases of apparent paresis would turn out to be cases of real paresis of the intestines. Anyone who had seen a severe case of intestinal paresis, and who believed he had an agent that would prevent its occurrence, would always use it. He asked attention to the way salts acted, drawing fluid from the patient's own vessels; in other words, one simply bled the patient into the intestines. He strongly advised them to *let the patient alone* after the proper use of eserine, until there appeared distinct indications for something to be done. With regard to diet, he had no rule to give. If the patient wished a full diet he usually got it. He cautioned against giving eserine in septic cases, because then one would possibly get an action that would prevent walling off of the condition by adhesions, or would break up existing adhesions. It was his custom to have the patients under observation for thirty-six hours prior to operation, when he gave a dose of calomel, followed next morning by a dose of salts. He was not insistent upon having a certain number of movements, but he kept working until the bowels had discharged the accumulations.

Philadelphia County Medical Society.

At a stated meeting, held January 11, Dr. Anna M. Fullerton read a paper entitled "Medical Experiences in India." She spoke of the great poverty of the people, of the evil results of child marriage, and of the disadvantage at which women are placed because of the prohibition preventing the medical attendance of men.

Dr. B. Franklin Royer read a paper entitled "The Antitoxin Treatment of Diphtheria." He cited statistics showing how marked in a number of the largest cities of the world had been the reduction in the mortality of diphtheria since the introduction and general employment of the antitoxin. He dwelt also on the prophylactic value of the antitoxin and he commended large doses.

Dr. M. Graham Tull read a paper, entitled "An Unusually Severe Case of Acute Chorea Treated Successfully with Apomorphine." He reported the case of a young girl presenting symptoms of chorea, with active delirium, which failed to yield to established treatment, but subsided almost immediately after the administration of apomorphine in small doses at frequent intervals was begun. Equally satisfactory results were obtained with the same drug in the treatment of other disorders, namely, alcoholic intoxication and capillary bronchitis in children.

Philadelphia Neurological Society.

At a stated meeting held January 24, Dr. Wm. Pickett exhibited "A Case of Cervical Hypertrophic Pachymeningitis" occurring in a young woman, who presented pain in the upper extremities, with weakness and wasting.

Dr. Chas. W. Burr exhibited "A Case of Epilepsy with Myoclonus." The patient was a young man who had had attacks of petit mal in early life, and later developed also attacks of grand mal. At times he would exhibit symptoms of great mental excitement, but the special feature he presented was jerky incoordinate movements in the face and extremities, occasionally with difficulty in walking. There were no distinctive symptoms of hysteria, although some of the manifestations were suggestive of that.

Drs. W. G. Spiller and E. U. Buckman exhibited "A Case of Myasthenia Gravis in which the Paresis is Confined to the Ocular Muscles." The patient was a man, 33 years old, occupying a clerical position, without a history of syphilis, who for some nine months had noticed a drooping of one or other upper eyelid and the development of diplopia, after use of the eyes. The conditions were better in the morning after rest, and became pronounced as the day progressed, quite disappearing when the patient lay in the recumbent position.

Dr. Joseph McCool read by invitation a paper entitled "Four Cases of Beriberi."

Dr. T. H. Weisenburg read a paper entitled "The Pathology of Cerebellar Tumors."

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending February 4, 1905:

	Cases.	Deaths.
Measles	185	[illegible]
Diphtheria and Croup	311	49
Scarlet Fever	233	15
Smallpox	1	1
Chickenpox	135	[illegible]
Tuberculosis	343	180
Typhoid Fever	32	10
Cerebrospinal Meningitis	[illegible]	33
Typhus Fever	[illegible]	[illegible]
Yellow Fever	[illegible]	[illegible]
Cholera	[illegible]	[illegible]
Totals	1,240	296

The Protozoön of Scarlet Fever.—Charles W. Duval has undertaken a search for the protozoön-like bodies, discovered by Mallory in the skin of autopsied scarlet fever cases, in the fresh serum of scarlet fever patients. He believed that if these "bodies" lying free in the intercellular lymph spaces represented stages in the life cycle of a protozoön they could be drawn into the contents of an artificially produced vesicle. In all, eighteen cases were studied. The protozoön-like bodies were found in five cases among those last examined and during the stage of the disease when the eruption was at its height. The majority of the "bodies" found in the serum were identical in structure and in form with those in the skin described by Mallory. The protozoa were not found in the vesicle contents of normal individuals. Moreover, a careful search of the contents of artificial vesicles produced on chemically injured skin failed to show them. Again, the "bodies" were not found in the serum from artificial vesicles produced on the skin of other acute exanthemata. The writer describes the production of the vesicle as follows: A bit of sterile absorbent cotton, about 2 cm. in diameter, is saturated with ammonia and closely applied to the selected skin area. In from two to five minutes the patient feels a "biting" sensation, and the cotton is removed, and the area carefully coated over with sterile vaseline. This is left until the vesicle is fully developed. This is complete in five or six minutes. The vaseline is dissolved off with xylol. From the vesicle, a clear, straw-colored serum, free from red blood cells and leucocytes, is obtained. It is drawn off at once by means of a bent sterilized glass pipette, by inserting the capillary tip into the base of the vesicle at the upper side, to avoid loss of serum. A full reports of this work will appear later.—*University of Pennsylvania Medical Bulletin.*

The Prognosis of Epilepsy.—William Aldren Turner says that sex plays little part in the general prognosis of epilepsy. It appears that a larger percentage of women escape the deteriorating influence of epilepsy upon the mind than men, but that when dementia supervenes and reaches its most pronounced form, a somewhat higher percentage of women are affected. A family tendency to either epilepsy or insanity materially increases the likelihood of the disease becoming confirmed, and the supervention of dementia. Epilepsy beginning in infancy and childhood is the least favorable for arrest of the fits and the most favorable for the production of the confirmed disease. The common type of epilepsy, or that commencing during puberty, is the most favorable form of epilepsy, both as regards the arrest of the seizures and the absence of mental infirmity. Adult epilepsy is unfavorable, but senile epilepsy is tractable. In general, the earlier a case is brought under systematic treatment, the more hopeful the prognosis and the greater the probability of improvement. The longer the interval between the attacks, the greater the prospect of arrest or improvement. Major attacks are more readily influenced by drugs than the minor seizures. Remissions are a frequent, if not a characteristic feature of this disease. Long remissions may occur under bromide administration, to be followed by a relapse when the drug is omitted. Again, a remission of long duration may be broken by an accidental circumstance, such as a fall or a blow on the head. Thus, long periods of arrest, though as a rule indicating a favorable prognosis, are not synonymous with the cure of the disease. It may be said that epilepsy is sometimes cured. The writer regards it unsafe to consider any case cured in which the seizures have been in abeyance for a period less than nine years after the disease has become satisfactorily established. A very small percentage of cases do relapse after an arrest of nine years. If any given case of epilepsy is capable of improvement, a satisfactory response will be apparent within a short time of commencing treatment. The writer gives a series of cases of a total of 147, of which 15 were arrested for nine or more years, giving a percentage of 10.2 of cures.—*The Edinburgh Medical Journal.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon General, Public Health and Marine Hospital Service, during the week ended February 3, 1905:

A REPORT OF EIGHTY-FOUR OPERATIONS ON THE KIDNEY AND URETER.*

BY GEORGE EMERSON BREWER, M.D.,
NEW YORK.

PROFESSOR OF CLINICAL SURGERY, THE COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA UNIVERSITY.

THE writer's experience in renal and ureteral surgery extends over a period of ten years and consists in eighty-four operations. Nine only of these operations were performed during the first five years; seventy-five during the last five years, and of these thirty-nine were performed within the past twelve months. The object of this communication is to present a report on the results of these operations, to enumerate the pathological conditions found, and to call special attention to certain groups of cases which presented features of unusual interest or difficulties in diagnosis.

Of the eighty-four operations there were twenty-seven nephrotomies, with eight deaths; twenty-seven nephrectomies with one death; nine nephrorrhapies with no mortality; ten decapsulations on five patients, with two deaths; five operations on the pelvic portion of the ureter without a death, and six emergency operations on traumatic cases with one death.

Of the twenty-seven nephrotomies the following pathological conditions were found at operation: pyonephrosis in three cases, pyelonephritis in one case, tuberculosis in two cases, intermittent hydronephrosis in one case, multiple septic infarcts in four cases, calculus in eleven cases, while in five cases of exploratory nephrotomy no lesion was found.

Of the twenty-seven nephrectomies there were two cases of primary carcinoma, two cases of hydronephrosis, two cases of early tuberculosis, seven cases of pyonephrosis, six cases of stone, two cases of ureterovaginal fistula following hysterectomy, one case of septic pyelonephritis, one case of general infection following traumatic rupture, one case of early rupture, one case of severe hemorrhage following exploratory nephrotomy, and two cases of multiple septic infarcts from blood infection.

As these two groups deal largely with the same classes of lesions, and as there is still much doubt in the minds of surgeons regarding the choice of operation in many cases, they will be considered together.

Carcinoma.—CASE I.—A young man, thirty-three years of age, referred to the writer by Dr. W. L. Culbert, of this city. First symptom: spontaneous hematuria followed by left-sided pain of a very mild character; two months later another attack of a similar nature. Examinations: slight tenderness in the left costovertebral angle; kidney not palpable. Cystoscope showed clot adherent to the left ureteral orifice. Ureter could not be catheterized. On operation a large, highly vascular kidney found presenting pronounced outgrowth on upper half. Nephrectomy. Pathological report, adenocarcinoma involving upper half of organ, but not perforating capsule. Patient now well four years and ten months after operation.

CASE II.—Naval officer, fifty-nine years of age, referred by Dr. John Stanton of New London. First symptom, right-sided colic followed by hematuria, three attacks in six weeks. Physical examination negative; *x*-ray showed only extreme calcification of all the arteries. Nephrectomy. A small nodule of carcinoma was found in upper half of organ. Convalescence normal. Last seen eight and one-half months after operation. No signs of recurrence.

Tuberculosis of Kidney.—Four cases of primary tuberculosis of the kidney were operated upon, two by nephrectomy and two by nephrotomy. Of the two operated upon by nephrotomy one proved to be a case of general miliary tuberculosis presenting signs of acute general sepsis with pain over the kidney as the only localizing symptom. The kidney was exposed and incised and found to be studded with small abscesses. The second case was one of tuberculous pyonephrosis, which was opened and drained. Both patients died within two weeks after operation from uremia. In both instances the condition was supposed to be of septic rather than tuberculous origin, and the opposite kidney was assumed to be functionally competent. In neither case were the separated urines examined. Had this been done, a correct diagnosis would have been made.

Of the two operated upon by nephrectomy, one, a boy seventeen years of age, had well marked signs over the left kidney, with pus and tubercle bacilli in the urine secreted by that organ. The other patient, referred by Dr. O. T. Osborne, of New Haven, also a boy seventeen years of age, had complained only of malaise and slight afternoon fever for several weeks. An examination of the urine showed a few pus cells and tubercle bacilli, which were later found only in the urine drawn from the right ureter. Both submitted to nephrectomy and both made satisfactory recoveries.

Pyelonephritis.—Two cases of acute septic pyelonephritis were operated upon—one by nephrotomy and drainage and one by nephrectomy. The former patient died, while the latter recovered. The fatal case was one of my earliest, and as my records are defective, no data could be found to help us to determine the cause of death.

Pyonephrosis.—Ten operations were performed for conditions supposed to be pyonephrosis, three nephrotomies and seven nephrectomies.

Of the three treated by simple incision, the first case was in an old man, who was admitted to the Mt. Sinai Hospital suffering from grave septic symptoms, with the signs of an enlarged and painful kidney on the left side. The kidney was exposed by a free lumbar incision and an opening made through its cortex, evacuating about a pint of pus. The septic symptoms were at once relieved, but the sinus showed no tendency to heal. Several weeks

*Read at a meeting of the Surgical Section of the New York Academy of Medicine, January 6, 1905.

later he submitted to a secondary nephrectomy, which was followed by a complete recovery.

The second case was in a young man about thirty years of age who was referred to me for treatmnet of a supposed left-sided empyema. There was flatness over the left chest wall as high as the angle of the scapula. An exploring needle inserted in the eighth intercostal space drew creamy pus. A more careful examination, however, showed a large left-sided abdominal tumor bulging the flank, which was oval in shape with well-defined borders, and apparently moved with respiration. The tumor was exposed by a large Koénig incision, an aspirating needle introduced and the presence of pus demonstrated. An incision was then made through what was supposel to be the cortex of a huge pyonephrotic kidney, and nearly two quarts of pus evacuated. A large rubber drainage tube was introduced and the wound closed. He made a satisfactory recovery from the operation, but an abundant discharge of pus continued for several weeks, which led us to advise nephrectomy. On entering the retroperitoneal space we were surprised to find that the original pus cavity was not the pelvis of the kidney but an enormous suppurating cyst, which arose from the anterior surface of the organ. Both cyst and kidney were removed, and the patient made a prompt recovery. The specimen was unfortunately lost, but from gross appearances the writer is of the opinion that the lesion was probably a suppurating echinococcus cyst.

The third case was one of extraordinary interest, not only on account of its obscure etiology, but on account of the anatomical conditions found at operation. The patient, a man forty years of age, was referred to the writer by Dr. N. R. Hotchkiss of New Haven. There was a history of a gradual deterioration of health for several months associated with loss of weight and an increased frequency of urination. For several weeks before he was seen by the writer there had been irregular attacks of fever followed by the presence of a large quantity of pus in the urine. As the symptoms progressed, it was noticed that there would first be a period of pain in the left flank with a tender mass in the kidney region associated with chills, fever and sweats—the urine remaining comparatively clear. Finally the urine would appear loaded with pus, the pain and fever would subside, and the mass would disappear. During this period the urine always contained a quantity of sugar. Roentgen-ray examination showed a very faint shadow over region of left kidney. A diagnosis of intermittent pyonephrosis from calculus was made and operation advised.

On exposing the kidney region by incision, all the tissues were so infiltrated with inflammatory exudate that recognition was extremely difficult. After incising the muscular layers, however, a fluctuating mass presented having the appearance of renal cortex. This was incised and about one pint of thick pus evacuated. As the patient's condition was extremely critical, no further exploration was made. The cavity was drained by a large rubber tube and the wound partly united and dressed. All of his symptoms were at once relieved, the pain and fever subsided, the pus disappeared from the urine, and the excretion of sugar ceased. He gained rapidly in strength and weight. Believing that he had a very much damaged kidney, which would undoubtedly give more trouble, I advised nephrectomy.

On exposing the kidney region for the second time the same matting together of the tissues was noted as at the first operation. As no kidney was found, the incision was enlarged and the tissues were carefully separated until the quadratus and psoas muscles were exposed and the transverse process of the vertebra could be felt. The entire retroperitoneal space from the diaphragm to the brim of the pelvis was thus exposed without encountering any tissue which resembled a kidney. During these manipulations the peritoneum was divided and an oval bluish organ seen under the costal arch, apparently presenting an almost complete peritoneal investment. Assuming this to be the spleen, it was held out of the way by gauze packing and the search continued. When it was evident to all that the retroperitoneal space contained no kidney, this intraperitoneal organ was again examined and as the spleen could be palpated beyond and above this mass, it was drawn outward and found to be the kidney which had evidently been pushed inwards by a large perinephritic abscess, and received its peritoneal investment from the posterior parietal layers of that membrane. As the abscess had on several occasions evacuated itself through the urinary passages, I assumed that it had arisen primarily in the kidney, or at least had a distinct communication with it or the ureter, and therefore performed a hasty nephrectomy. Examination of the specimen showed only an almost healed scar in the posterior surface which was in contact with the abscess cavity. On splitting the organ there was only the appearance of a moderate cloudy swelling of the parenchyma with no stone or suppurating focus.

As the other cases of this series presented no features of special interest, they will not be reported in detail.

Multiple Septic Infarcts from Blood Infection.—That the kidney may be the seat of multiple metastatic abscesses as a result of a general pyemic process, the abscesses being caused by numerous septic emboli conveyed to the organ by the blood current, is a fact well recognized by the profession; that a single kidney may be the chief seat of such lesions—the opposite kidney and other organs escaping or being but slightly involved—is a fact not generally recognized by the profession. That such is the case, and that an early nephrectomy constitutes the best treatment for this condition, the following facts will attest: Six cases of multiple blood infections have been operated upon by the writer, four by nephrotomy, all fatal, and two by nephrectomy, both recovering.

Case I.—A girl eighteen years of age, sustained a fracture of both thighs, no signs of other injury. Three weeks later, during an apparently normal convalescence, she complained of pain in the right renal region radiating downward to the groin and labium. This was followed by a rapidly advancing fever, chills and sweats. There was marked tenderness on bimanual palpation over the right kidney; the urine was scanty, albuminous, and contained a few pus cells. The symptoms continued for several days and her general condition became alarming. No other septic focus could be discovered. On exposing the kidney through a lumbar incision, it was found studded with small cortical abscesses and was highly congested. It was removed from the wound and bisected—several small abscesses were found and innumerable minute infarcts. The hemorrhage was severe and only controlled by replacing the kidney, packing the incision tightly and the entire space around the organ. She died the following day.

Case II.—A woman thirty-one years of age presented the symptoms of severe general sepsis and tenderness over the right kidney. On operation the kidney was incised and found to be the seat of multiple minute cortical abscesses. The wide kidney incision was drained with a large gauze pack and the organ replaced. She died the following day. Autopsy showed a general pyemia.

Case III.—A young woman, seen at the City Hospital with general septic symptoms and pain and tenderness over one kidney. Nephrotomy; multiple abscesses. Death.

Case IV.—Man, twenty-one years of age, complained of general abdominal pain and frequent micturition with hematuria. The symptoms temporarily subsided, but three weeks later the pain became localized over the right kidney region and was accompanied by a gradually rising temperature and other symptoms of progressive sepsis. On examination, there was tenderness and some muscular rigidity in the right flank, the urine was albuminous and contained some pus, a few red blood cells and casts. No evidences of other septic foci could be found. The right kidney was exposed by a lumbar incision and freely opened by a cortical cut. The entire parenchyma was studded with minute abscesses. Gauze drainage was inserted, the incision partly closed and the wound dressed. There was considerable temporary improvement in the symptoms, but this improvement was succeeded by a gradual return of the septic manifestations with diminution in the secretion of urine, and death three weeks later. On autopsy a general pyemic condition was found with numerous but more recent infarcts in the other kidney.

Case V.—A woman, aged twenty-eight years, experienced an attack of chills, fever and general prostration and was treated for malaria. An examination of the blood revealed no plasmodia, and upon subsequent examination an enlarged and tender right kidney was easily palpated. Under chloroform anesthesia the kidney was explored and incised. The cortex was studded with small areas the exact nature of which could not be determined at the time. The organ was removed and on subsequent examination was found to be the seat of numerous infarcts. She made a complete recovery.

Case VI.—A woman, twenty-two years of age, experienced a severe pain in the epigastrium and right side of abdomen, with vomiting and high fever. Was sent to the Roosevelt Hospital with a diagnosis of acute appendicitis. On examination the appendix region was free from evidences of inflammation. There was, however, pain and muscular rigidity in the right hypochrondiac region with tender points over the gall-bladder and costovertebral angle. Temperature 105°, pulse 120, leucocytes 18,000. The urine was slightly albuminous—no blood or pus. The diagnosis rested between an acute infection of the gall-bladder or kidney. Small anterior incision; gall-bladder and liver found normal, but the right kidney seemed enlarged. Anterior incision united and the kidney explored by the lumbar route. The perinephric fat and areolar tissue was edematous; the kidney enlarged, highly congested and the seat of innumerable small infarcts. Nephrectomy. After operation the temperature fell from 105.5° to 97° within twelve hours, and thereafter remained practically normal. She made a satisfactory convalescence. Microscopical examination of the specimen showed it to be filled with minute embolic abscesses.

As the cases of hydronephrosis, uretrovaginal fistula, severe hemorrhage following nephrotomy, etc., presented no difficulties in diagnosis, they will not be considered at length. We will therefore pass to the consideration of those cases in which calculus was suspected, as that group of cases furnishes the largest number of mistakes in diagnosis. With this group it is well to consider also the five cases in which operations were performed on the lower or pelvic portion of the ureter, as in all of these the diagnosis of arrested calculus had been made.

It might be said that in nearly every case subjected to nephrotomy or nephrectomy, the possibility of calculus as a causative factor was considered; as the chief complaint in the majority of those cases was lumbar pain. In eliciting the histories, however, we were able to exclude at once a number of cases, and although many of these were subjected to an *x*-ray examination, cystoscopy and catheterization of the uterers, we shall not include them in this group for the reason that the history clearly pointed to another diagnosis.

In thirty-six cases, however, the history led us to strongly suspect the presence of calculus either in the kidney or ureter. In twenty-one of them only did subsequent operation reveal a stone. In the remaining fifteen, nine showed other lesions which clearly were the causative factors in the production of the symptoms, while in six no lesion could be found.

It will thus be seen that in 41 per cent. of our cases giving a clinical history of calculus, and this in many instances confirmed by physical signs, urinary analysis, cystoscopy, uretral catheterization, and in a few by a positive *x*-ray plate, our diagnosis was wrong.

It is only fair to say in this connection that during the earlier years of the writer's experience, before the discovery of the *x*-rays, and before the general employment of the cystoscope and ureteral catheter, reliance was placed wholly upon the history, physical examination of and the urinary analysis. During the first six or seven years covered by this report, the number of errors in diagnosis in this class of cases was relatively greater than during the last few years, in which the modern methods of examination have been employed with increasing frequency.

Being impressed with the large percentage of errors in diagnosis in this class of cases, I have carefully reviewed the histories of the thirty-six cases in which the diagnosis of calculus was seriously entertained, to find, if possible, the cause or causes of these mistakes.

We will therefore consider (1) the subjective symptoms, as pain, frequent and painful micturition, vomiting; (2) the objective symptoms, as fever localized tenderness, and the presence of a renal tumor; (3) the results of urinary analysis with reference to hematuria and pyuria; (4) the results of *x*-ray examination, and (5) the results of cystoscopy and ureteral catheterization.

Pain is, perhaps, the most constant and characteristic symptom of renal stone. It was present in some form in twenty of the twenty-one cases in which stone was found at operation. Its absence was not recorded in a single instance, but the history is defective in one case. Regarding the character of the pain, it is somewhat difficult to classify the cases, as it frequently changed during the progress of the disease. I have therefore made four classes: (1) severe paroxysmal pain, radiating downward from the kidney along the course of the ureter—the typical renal colic; (2) mild paroxysmal pain, radiating less constantly downward; (3) severe constant pain, backache; (4) mild constant pain or discomfort. Of the twenty-one cases in which stone was found, thirteen had severe paroxysmal pain, or typical renal colic, four had mild paroxysmal pain; one had severe constant pain; two had only mild constant pain.

In three of the thirteen cases having severe paroxysmal pain it began in the epigastric region, shifting later to the region of the kidney and continuing thereafter in that location.

In the two cases complaining only of mild constant pain, one had an open sinus from a previous nephrotomy, leading to a pelvis full of stones, and

the seat of a purulent inflammation; the other patient was profoundly septic from an enormous pyonephrosis.

The point of greatest intensity of the pain was not infrequently located somewhat below the kidney, in several instances at or near McBurney's point on the right side, or at a corresponding point on the left. This was particularly the case in a patient with a stone which frequently became impacted in the upper portion of the ureter and was found there at operation; also in another case where a small stone was found in a calyx at the upper pole of the kidney. Both of these cases had been subjected to operation for the removal of the appendix. In a third patient, who also underwent the operation of appendectomy, the cause of the inguinal pain was found to be a stone arrested in the lower ureter near the bladder.

In three other cases of stone arrested in the lower ureter, the point of greatest pain and tenderness lay below McBurney's point, about one inch above the external abdominal ring. This was also the case in a patient in whom the *x*-ray constantly showed a shadow over the lower ureter but in whom no operation had been performed. In this case and in one other of stone in the lower ureter (both females) there has been a numbness at times of the labium on the side corresponding with the lesion. In one case of stone in the lower ureter, there was a constant pain near the umbilicus with occasional attacks of acute paroxysmal pain in the kidney.

Of the fifteen cases in which no stone was found at operation, five had severe paroxysmal pain; one mild paroxysmal pain; five severe constant pain; one mild constant pain, while in three the history is defective.

Of the five cases with typical renal colic, one had an intermittent hydronephrosis from movable kidney, one a chronic interstitial nephritis, one an acute blood infection with multiple abscesses, while two presented no discoverable lesions of the kidney or ureter. In addition to characteristic and unusually severe renal colic, these two patients also had vomiting, and the presence of blood in the urine. The cystoscope showed in each instance an edematous and everted ureteral meatus, into which a catheter could not be made to enter. The *x*-ray in one case showed a dimly-defined shadow over the lower ureter, in the other no shadow in three exposures.

Of the other patients, one with mild paroxysmal pain had a perinephritic abscess. The *x*-ray in this case led us astray by showing a distinct shadow in the renal region (only one exposure). Two patients with severe constant pain showed no lesion of the kidney, two had suppurative disease of the kidney, and one had a chronic diffuse nephritis with intermittent hematuria coming from the ureter corresponding with the painful and tender kidney.

The case with mild constant pain, which was located over the lower ureter, showed on *x*-ray examination a distinct shadow in the pelvis. Operation revealed the presence of a large calcareous body adherent to but outside the ureter, near the bladder.

Vomiting was found to be a very constant accompaniment of severe colic. Of the twenty-one cases where stone was found, eleven had vomiting, nine had no vomiting, and in one the history was defective. Of the fifteen cases in which no stone was found, vomiting occurred in seven, was absent in four, and unrecorded in four cases. That it is not a very reliable symptom of calculus will be appreciated when we observe that it occurred in a greater percentage of the cases in which no stone was found.

The combination of severe vomiting associated with violent epigastric pain is misleading, and in the writer's experience has once led to an unnecessary laparotomy. Severe colic due to stone in the lower ureter is less likely to be accompanied by vomiting than in those cases in which the lesion is in the upper ureter or kidney.

Frequent or painful micturition, occasionally associated with severe tenesmus, was present in twelve of the twenty-one cases of stone; it was absent in seven and unrecorded in two. In the cases without stone it was present in four, absent in seven and unrecorded in four cases. Of five cases of stone in the ureter, this symptom was constantly present. If we exclude these, it will be found to be present in one-half the cases of stone in the kidney. This fact would tend to disprove the statement made several years ago by Bryson, that lesions of the kidney and upper half of the ureter rarely give rise to frequent or painful urination.

Fever is rarely a symptom of uncomplicated stone in the kidney or ureter, but is frequently present where infection is added. It was present in eight of the twenty-one stone cases, absent in twelve, and unrecorded in one. Of the eight cases in which it was present, all had pyuria or other evidences of septic infection.

Mild and even moderately severe cases of calculus pyelitis will often run a normal temperature while the ureter remains patent, but will show an immediate rise in temperature if for any reason the ureter becomes occluded. This occurred in four cases of my series, in two of which the stone became impacted in the upper part of the ureter, and in two others in which the stone was arrested low down in that canal, and temporary occlusion was probably caused by some change in its position.

Of the fifteen cases in which no stone was found, fever was present in four, absent in seven, and unrecorded in four. In this group also fever was present only when infection was known to exist.

Tenderness was present in every case of stone in which the history was preserved, thus in twenty of the twenty-one cases, its presence is recorded. In sixteen cases it was present in the region of the kidney, best elicited by bimanual palpation or by firm pressure in the costovertebral angle. In one instance, the tenderness existed over the ureter, the stone being subsequently found in the kidney; in another the tenderness was chiefly over the kidney, the stone being found in the lower end of the ureter. In three other cases of stone in the lower ureter, tenderness was most marked from one to two inches above the external abdominal ring.

Of the fifteen cases in which no stone was found, eleven had renal tenderness, while in the remaining four the records do not mention it.

As tenderness is generally present where severe spontaneous pain is felt, and as in at least three cases of this series which showed no stone or inflammatory lesion marked tenderness existed, too much reliance must not be placed on this symptom.

Renal Tumor.—In only eight of the twenty-one cases could the kidney be palpated, while in twelve it could not be felt, one case being without a record. In three only of the negative cases was the kidney palpated, one of these being the intermittent hydronephrosis. In the remaining twelve this sign was either absent or unrecorded.

While the presence of an enlarged and tender renal tumor must be regarded as almost positive evidence of some lesion of that organ. The absence of this sign should not militate against the diagnosis of stone, as it is rarely encountered in uncomplicated cases of renal calculus.

Hematuria.—While blood is probably present in

the urine at some period in nearly every case of renal or ureteral stone, it is often in such small amount as to be detected only by the microscope; moreover it is often entirely absent at the time of a given examination. Of my twenty-one stone cases, ten had blood in the urine, nine had none, and in two the history is defective. Of the ten cases in which blood was found, in seven it colored the urine so that it was noticed by the patient. In three it was found only by the microscope.

Of the fifteen cases in which no stone was found, five had hematuria, six had no blood and in four it is not recorded.

Of the five cases of hematuria, in three the blood was seen only by the microscope, in one it was seen by the cystoscope, issuing in a long worm-like clot from the ureter; in the remaining case, in which the hemorrhage was abundant, the lesion proved to be chronic unilateral hemorrhagic nephritis. Of the three cases in which microscopic blood was found, one was an acute pyelonephritis, one was an acute blood infection of the kidney, and the remaining one showed no lesion at operation, although there is much reason to suspect that in this as well as in the case in which blood was seen by the cystoscope issuing from the ureter, a stone was present in the ureter and passed just before operation. In calculus cases, one is apt to find traces of blood during or immediately after a paroxysm of colic.

In one instance, after watching for several weeks a patient who complained of severe attacks of paroxysmal pain and vomiting, the pain being referred to an area about the size of a silver quarter, one inch to the inner side of McBurney's point, I was able to make a correct diagnosis by observing a few red blood cells in a specimen of urine passed immediately after a paroxysm. This led me to make a second exploration of the kidney (the first exploration being performed by another surgeon several months before). At the second nephrotomy, a small calculus was found completely plugging the pelvic extremity of the ureter.

Pyuria.—The presence of pus in the urine is dependent upon so many factors, that it is of very little value in the diagnosis of renal or uretral stone.

The presence of a stone in the uninfected pelvis of the kidney or ureter does not give rise to a purulent secretion. That pus is often present—due to infection—is evidenced by the fact that in sixteen of our twenty-one stone cases, pyuria was noted, in four it was absent, and in one it was unrecorded. It was also present in four of nine cases where stone was not found.

The presence of pus in the urine from one kidney and its absence from that drawn from the other by ureteral catheterization, is of course a valuable sign of renal infection.

Cystoscopy and Catheterization of the Ureters.—To the employment of the cystoscope and ureteral catheter surgery owes much for the advances which have been made both in the diagnosis of affections of the urinary passages, and in determining the competence of the other kidney in contemplated operations.

Some five years ago I began to employ these instruments—at first irregularly and often unsuccessfully. During the past eighteen months, however, since Dr. Klotz has given his services to the hospital in this department, our results have been far more reliable and satisfactory. It is only during this latter period that accurate records of our findings have been kept.

Without entering into the details of our subject, I will simply report that in our cases of suspected calculus, thirteen cystoscopies and ureteral catheterizations have been made.

Number of cases showing typical appearances of the ureteral meatus of catheter findings, and in which stone was afterwards found on operation—five.

Number of cases in which meatal appearances suggested calculus but in which no stones were found at operation—two.

Number of cases in which catheter findings indicated renal lesion but not necessarily stone—four.

No cystoscopic or catheter evidences of stone, no stone subsequently found—one.

Generally unsatisfactory—one case.

X-ray Examinations.—This in competent hands is, in the writer's opinion, the most valuable method of examination which we possess for the diagnosis of calculus disease of the kidney or ureter. During the past five years it has been constantly employed at the Roosevelt Hospital in the routine examinations of cases of suspected stone. As most of our earlier attempts were unsatisfactory, and as the records during that period are exceedingly imperfect, the data which I will present cover only a period of two or three years, since the department has been under the direction of Dr. L. G. Cole.

Of our twenty-one cases of stone, *x*-ray examinations are recorded in twelve, of which ten were positive and two negative—the two latter being in an exceedingly corpulent individual with stones in both kidneys, which did not show in the plates.

Of the cases which did not have stone, an *x*-ray examination was made in six instances, three of which were negative and three gave shadows and led to erroneous diagnosis. Of these last three one was in the kidney region but without clearly defined edges, one over the pelvic portion of the ureter, also without clearly defined edges, and one other over the lower ureter with clearly defined edges. In this instance a calcareous mass was found adherent to, but outside the ureter, and upon examination proved to be the calcified tip of an appendix epiploica, which had become adherent by inflammatory exudate to the parietal peritoneum over-lying the ureter.

If we follow the advice of Dr. Cole, and reject all plates which do not show the outline of the psoas muscle and the transverse processes of the lumbar vertebræ, and look with suspicion on all shadows which do not have well-defined edges, only one error would have been made in this series of cases.

Several sources of error must always be considered in plates of the pelic cavity, namely: calcified lymph nodes, phleboliths, calcareous masses in the sacrosciatic ligament, and calcified appendices epiploicæ, which have not to my knowledge been observed before.

From a careful review of the above facts, I feel justified in stating that there is no single symptom nor sign, nor any group of symptoms or signs that is absolutely pathognomonic of renal or ureteral calculus, unless the calculus lies in the lower ureter and can be touched by a metal bougie or catheter.

The most important factors to be considered in making a diagnosis are pain, tenderness, hematuria, the results of radiography, cystoscopy, and ureteral catheterization.

While vomiting, vesical irritability, pyuria, fever, and the presence or absence of a renal tumor are important, and will often help us to confirm or lead us to exclude other pathological conditions, too much reliance must not be placed upon them in the diagnosis of calculus.

While pain and tenderness were present in practically 100 per cent. of our cases of stone, it must not be forgotten that they were also present in a large percentage of the cases in which no stone was

found. That calculus may, and often does exist without pain, is evidenced by the statement of Bruce Clark, who reported twenty-four autopsies upon calculus patients—in thirteen of which there had been no subjective symptoms during life.

Hematuria was known to be present in 52 per cent. of our stone cases, but it was also present in 45 per cent. of the cases without stone.

Spontaneous hemorrhage occurring during rest and sleep, generally means new growth. Hemorrhage following active exercise or jolting, and accompanied by characteristic colic, in the absence of other demonstrable pathological conditions is strongly suggestive of calculus.

If we include all cases examined, the *x*-rays gave positive evidence of the presence or absence of stone in 72 per cent. of our cases. If we exclude the imperfect plates and those in which the edges of the shadow were not distinctly defined, it gave accurate indications in 95 per cent. of our cases, and must therefore be regarded as the most reliable means of examination which we possess.

Cystoscopy by enabling us to observe the conditions of the ureteral orifices, helped us to a correct diagnosis in 66 2-3 per cent. of the cases examined, while it was misleading in 33 1-3 per cent.

Ureteral catheterization proved valuable in confirming our diagnosis, in definitely determining the side of the lesion, and in estimating the competence of the opposite kidney. It might be of positive value in certain instances by enabling the surgeon to touch a ureteral stone with a metal catheter or bougie in the female. It might also be useful with the *x*-rays, by introducing a catheter bearing a metal stylet into the ureter, to determine the probability of a given shadow being within or without the canal, although this might lead to error if the object causing the shadow lay in front or just behind the ureter, as in my case where a calcified appendix epiploica lay just in front of the terminal portion of the ureter.

As my series of nephrorrhaphies presents no features of special interest, and as I am unable to report any recoveries after the operation of decapsulation for chronic nephritis, I will pass at once to the traumatic cases. Of these there were six.

Case I.—The patient sustained a fracture of the liver and kidney from a severe blow on the right loin. Abdomen opened and found full of blood, liver wound packed. Kidney lesion recognized from the presence of hematuria and a large retroperitoneal exudate, but the condition of the patient precluded the possibility of further exploration. Death. Autopsy revealed extensive rupture of right kidney.

Case II.—Male, received a severe blow over right flank; two lower branches of the renal vein torn off with but slight injury to renal parenchyma; extensive retroperitoneal hematoma. Kidney explored by lumbar incision, veins clamped and ligated. Recovery with functionating kidney.

Case III.—Severe contusion of kidney with superficial lines of fracture radiating from pelvis; moderate perirenal hemorrhage. Kidney explored; gauze drainage; recovery.

Case IV.—Child, received a blow over left loin; moderate hematuria, no pain or discomfort; moderate fullness of flank, and tenderness on palpation. Kidney explored by lumbar incision; complete transverse rupture at junction of upper and middle thirds, involving the pelvis; suture; recovery.

Case V.—Child with a transverse rupture of the kidney about middle, with considerable contusion and hemorrhage. Kidney sutured; wound packed. Infection followed requiring a secondary nephrectomy; recovery.

Case VI.—Colored man, aged twenty-eight, fell from a height injuring his left side and abdomen. Hematuria immediately after injury; second specimen of urine clear. Complained of pain and soreness in left flank; moderate tenderness and slight fullness; no shock. Several hours later complained of sharp abdominal pain, vomited and became restless and thirsty. Second examination showed abdominal muscles rigid, free fluid in peritoneal cavity, an increased fullness in left flank. Pulse 120, temperature 101°. Under ether anesthesia the abdomen was opened and found full of fluid and clotted blood, stomach, intestines, liver, and spleen examined with negative result. Abdominal cavity thoroughly irrigated with hot salt solution and wound closed. Patient's condition becoming alarming an intravenous saline infusion was given, also strychnine and other stimulants. Left kidney exposed by lumbar incision found to be divided by two transverse ruptures into three unequal portions—one of which lay free in the large collection of fluid and clotted blood; the other two were attached to the vessels forming the pedicle. The pedicle was clamped and the renal tissue hastily removed and the wound packed. Slow recovery from shock; no febrile reaction. Pedicle clamp removed on the eleventh day. Recovery.

As extensive injuries to the kidneys may occur with but slight local or general symptoms, I have been led to adopt the rule that all cases of severe contusion of the flank with hematuria should be immediately explored.

In conclusion, I desire to state that in estimating the competence of the opposite kidney in contemplated operations, use has been made occasionally of the methylene blue test—more frequently of chemical and microscopical examinations of the separated urines obtained by the Harris segregator or ureteral catheterization, and also of late with increasing frequency, of cryoscopy, or determining the freezing point of the blood serum and of the urine.

STANDARDIZED GRUELS: AN APPLICATION OF THE PERCENTAGE PRINCIPLE TO GRUEL FEEDING.*

By HENRY DWIGHT CHAPIN, M.D.,
NEW YORK.

During many years gruels have been used empirically for their known beneficial effects as a dilutent of cow's milk for infants. Jacobi and others have long been advocates of the use of gruels for the purpose of rendering the milk curds softer. With the increased knowledge that has resulted from a careful study of the use of gruels in infant feeding, it has become recognized that they have other values than those of attenuants of the curd of cow's milk. The effect they produce on the general process of digestion is often marked, and close studies of physiology, digestion, and metabolism show that they may often be employed to economize the energy of the body that is being used in the effort to prepare food for assimilation. By taking advantage of this fact it is often possible to keep the body well nourished on a quantity of food much smaller than is theoretically indicated. It has been clearly established that some forms of food require so much effort on the part of the body to prepare them for the use of the cells and tissues, that only a small portion of the food really is used to repair waste or build up new tissue, the larger portion being needed to furnish the energy for digestion and

* Read at a meeting of the Pediatric Section of the New York Academy of Medicine, January 12, 1905.

assimilation. In such instances an enormous amount of digestive work is performed with little resulting gain. In some forms of disease the energy of the body, which may be below normal, can be used to better advantage in fortifying the resisting powers of the organism than in carrying on the work of the digestive and assimilative processes. It is in these kinds of cases that it is advantageous to have some kind of nourishment that will be easily retained and quickly absorbed in a form that can be readily appropriated by the cells. Gruels have long been one of the forms in which such nourishment has been supplied. It is highly desirable, therefore, that there should be some uniform standards for use in preparing gruels and that their food values and possibilities should become better known.

For the purpose of establishing some such standards the writer had made a number of different kinds of gruels and then had them assayed to determine their composition in order to show the relative proportion of tissue-building and heat and energy-producing elements. Pearl barley, prepared barley flour, wheat flour and rolled or flaked oats, such as are sold in packages for family use, were used. The Pearl barley was boiled for three hours in a saucepan and then strained, a portion remaining on the strainer. The rolled oats were cooked for one hour in a double boiler and then strained, a portion also remaining on the strainer. The barley and wheat flours were cooked for one hour in a double boiler and strained, practically all of the flour passing through the strainer into the gruel. The gruels thus made were sent to the New York Agricultural Experiment Station where they were assayed by the courtesy of the director, W. H. Jordan and the following figures obtained:

	Total Solids.	Proteid (Nx6.25.)
Plain Gruels.		
1 oz. Avoir. Pearl Barley to quart (32 oz.)	1.483 per cent.	0.140 per cent.
1 oz. Av. Prepared Barley Flour to quart (32 oz.)	2.288 "	0.195 "
1 oz. Av. Wheat Flour to quart (32 oz.)	2.494 "	0.331 "
1 oz. Av. Rolled Oats to quart (32 oz.)	1.931 "	0.262 "
Dextrinized gruels.		
6 oz. Av. Rolled Oats to quart (32 oz.)	10.92 "	1.47 "
6 oz. Av. Wheat Flour to quart (32 oz.)	15.12 "	1.81 "

It will be noticed that the composition of the gruels made with six ounces of cereal to the quart is almost exactly six times the composition of the gruels made with one ounce to the quart.

If an ounce of cereal is made up into a quart of gruel and none of the cereal is removed by straining it is evident that each ounce of the gruel will contain 1-32 ounce of the cereal and that the cereal has been diluted 32 times. From this illustration it is easy to see that if a definite weight of cereal is used in making the gruel, and none of it is removed by straining, the composition of any gruel can be readily calculated by dividing the composition of the cereal by the number of times it is diluted. This rule cannot be followed in the cases of cereals which are not completely broken up by cooking and part of which is removed by straining. However, it will be noticed in the assays of gruels made from rolled oats that practically the same proportion was removed in the gruel made with six ounces as in the gruel made with one ounce of the oats, so this amount can be allowed for.

To determine on a convenient and accurate method of obtaining different weights of the cereals, the writer had twelve different trained nurses measure them with a tablespoon made level full by sliding a knife along the edges, and also with the author's one-ounce cream dipper and the quantities weighed. Inquiry of one of the largest manufacturers of spoons in the country brought out the fact that there is no accepted standard of size for tablespoons used, and that they vary slightly in capacity although all makers keep close to one size.

It may be safely accepted, however, that

1 level tablespoonful of	Pearl Barley	weighs	½	oz. Avoir.
1 " " "	Barley Flour	"	½	" "
1 " " "	Wheat Flour	"	½	" "
1 " " "	Rolled Oats	"	½	" "
1 Ounce Dipper	Pearl Barley	"	½	" "
1 " "	Barley Flour	"	½	" "
1 " "	Wheat Flour	"	½	" "
1 " "	Rolled Oats	"	½	" "

A sixteen ounce graduate of wheat flour weighs 8 ounces average, and the same measure of rolled oats weighs 5 ounces.

From these observations it is possible to construct a simple table for use in making gruels of any desired strength. Of course this table will not be absolutely accurate because the composition of cereals is not always uniform; and again, as the concentration of the gruels becomes greater, the increased specific gravity will slightly disarrange the calculated percentage composition. However, this table will be as accurate as the tables used in modifying cow's milk for infant feeding. The percentage methods of feeding as emphasized by Rotch are an advance in as far as they teach us to scrutinize food values. But the danger is of pushing the principle to an extreme that is liable to discredit the whole system, for undoubtedly many results that have been attributed to fine percentages have been due to other causes. It has been found that calculated milk food mixtures which gave good results when analyzed, did not have the calculated composition, and it is not to be reasonably expected that it could be otherwise, for exact results cannot be obtained unless each specimen of the milk is chemically analyzed, which is out of the question as some of the analytical processes are extremely complicated and laborious. In addition, extended experiments on animals, where perfect control was obtained, have shown that mathematical accuracy in composition of feeding mixtures cannot be made the basis of successful feeding. In considering cereal gruels in this table the only divisions made are proteids and carbohydrates. Cereals contain only small quantities of fat and mineral matter, and when made up into gruels the quantity of these elements actually present is so small as to not warrant their separate consideration on a percentage basis.

Approximate Percentage Composition of Gruels.

	Pearl Barley.		Barley Flour.		Wheat Flour.		Rolled Oats.	
	Proteids	Carbohydrates	Proteids	Carbohydrates	Proteids	Carbohydrates	Proteids	Carbohydrates
1 oz. to quart	0.14	1.34	0.195	2.093	0.331	2.161	0.262	1.669
2 " " "	0.28	2.68	0.390	4.186	0.662	4.322	0.524	3.338
3 " " "			0.585	6.279	0.993	6.483	0.786	5.007
4 " " "			0.780	8.372	1.324	8.644	1.048	6.676
5 " " "			0.975	10.465	1.655	10.805	1.310	8.345
6 " " "			1.170	12.558	1.986	12.966	1.572	10.014
7 " " "			1.365	14.651	2.317	15.127	1.834	11.683
8 " " "					2.648			13.352

Plain gruels cannot be made much stronger than two ounces to the quart.

Dextrinized gruels may be made as much as eight ounces to the quart.

The high proteid gruels are of great value in many diverse conditions. The author has employed them in persistent vomiting in patients of all ages; in the enfeebled digestive states accompanying typhoid and other fevers and in general exhausted conditions where the digestive and assimilative functions are at their lowest ebb.

There is a widespread erroneous belief that vege-

table proteids are not good tissue builders and are not readily digested. A moment's thought will show that they must be nutritious for the greater part of the animal tissues of the entire earth are built up from vegetable proteids. All of the lean meat of beef, mutton, and pork is derived from vegetable proteids. The proteid of bread is vegetable and it is almost entirely digested. Recent studies on the digestibility of bread, conducted under the supervision of Atwater,[1] in which correction for metabolic products in the feces was made, show that as high as 98 per cent. of the proteid of white bread is digested by men.

Rockwood[2] has shown that the proteid of oatmeal is as thoroughly digested as meat, if it has been separated from the fiber. The reason cereal proteids are apparently indigestible is that they are enclosed in cellulose which prevents the action of the digestive fluids; or the food is so coarse that it is hurried through the digestive tract and thus escapes the action of the digestive juices. Digestive experiments *in vitro* show the proteid of cereals to be easily digested if sufficient time is allowed. Cereals in the form of well cooked gruels have the cellulose ruptured, and so expose the proteids that they may be easily acted upon by the digestive enzymes.

TRAUMATIC RUPTURE OF THE INTESTINE WITHOUT INJURY TO THE ABDOMINAL WALL.*

By CARLETON P. FLINT, M.D.,
NEW YORK.

ATTENDING SURGEON TO THE LINCOLN HOSPITAL, CHIEF OF SURGICAL CLINIC OF THE ROOSEVELT HOSPITAL OUT-PATIENT DEPARTMENT, INSTRUCTOR IN SURGERY AT THE COLLEGE OF PHYSICIANS AND SURGEONS OF NEW YORK CITY.

During my service at the Lincoln Hospital, several cases of rupture of viscera without injury to the parieties have been treated by me; through the kindness of Prof. George E. Brewer, of the Roosevelt Hospital, opportunity has been afforded me to see several cases on his service at that institution, and thanks to the courtesy of several others I have been enabled to collect a series of reliable records from hospitals in and outside of New York.

The rarity of this accident and the well recognized difficulties in diagnosis led me to subject these cases and current literature to a more or less careful study. It may be noticed that the conclusions arrived at do not always correspond to the statements found in some of the standard works on surgery, where, however, the space devoted to this subject, even in the most recent books, is unduly scant.

Before entering upon a broader consideration of my theme I shall read the history of two cases which may serve in a drastic manner to emphasize the difficulties in diagnosis, and the great importance of prompt treatment in abdominal injuries of this character.

Case I (Author's). Frank Pacifico, aged 18, laborer. While he was engaged in sawing a board with a circular saw, something happened which threw the board back, striking him in the abdomen. The board was one inch thick, and 18 feet long. He walked about after the injury, but had some pain, and was given whiskey and water by his fellow laborers. Later he lay down to await the arrival of the hospital ambulance. He was admitted to the hospital at 11:20 A.M. and presented the following picture: A well developed and well nourished individual. Examination of the head, chest and extremities, negative; pulse 96, respiration 28, temperature 97.6°; the respiration was thoracic. His abdomen was normal in appearance. On palpation, it was found to be rigid, more so in the left upper quadrant, where there was some tenderness and pain. Almost in the median line just above the umbilicus was an irregular dull area and also a slight amount in the left flank. The center of the abdomen seemed somewhat more tympanitic than normal. Liver dulness intact. Urine negative.

The patient was seen by me for the first time about 1:30 P.M., that is, about two hours after the injury, at which time the clinical picture was the same except that his pulse had increased a few beats, and he had vomited once. Although the positive signs were not many, the expression of his face was that of a man with some serious condition, and on the strength of the abdominal rigidity, combined with the other symptoms and signs, an immediate operation was decided upon.

At 2:30 the abdomen was opened—approximately 3½ hours after the injury. There were 6 or 8 ounces of bloody fluid which smelt of whiskey, some intestinal contents, and a few blood clots.

The jejunum was torn in three places within four inches of each other and about one foot from the duodenojejunal angle. From these openings came intestinal contents. The mucous membrane protruded and the surrounding intestine was injected. A large laceration was found in the corresponding mesentery; also a large hæmatoma. The abdomen was quickly flushed out and the injured portion of the gut with its mesentery was resected, the ends of gut being united with a Murphy button over which the peritoneum was brought together with a continuous Lembert stitch. The edges of the mesentery were also adjusted with catgut and the abdomen was closed with through and through silkworm gut sutures. The duration of the operation was 25 minutes. The patient was given a small dose of morphine, and returned to the ward in good condition.

During the first four days he was fed by rectum and given small doses of opium to allay any discomfort and give the injured intestine a rest. There was a very moderate amount of postoperative distention, but the bowels moved in the evening and on the following days he passed gas freely. The temperature on the day after operation was 101.5°, and after that remained about 100° until the fourteenth day, when it suddenly rose to 104°. He had then been on liquid diet one week. On examination a deep resistance was made out on the left side below the umbilicus. On the next day the temperature was again 100°. Nevertheless, the mass persisted and the pulse was up. An exploratory incision was made and a small abscess opened on the left side of the mesentery. This contained thin pus, which was washed out. It had no fecal odor. The cavity was packed. This wound drained freely.

The temperature continued at about 100°. The patient ate well and felt well for about thirteen days more, when he began to have an afternoon rise of temperature. On examination a mass similar to the first was felt on the right side of the abdomen near the umbilicus. The symptoms were very slight, the local pain and tenderness was not marked, and there was very slight resistance. I decided that an abscess similar to the one opened two weeks previously had formed, and determined in the absence of any acute

*Read by invitation before the Clinical Society of the Elizabeth Hospital, Elizabeth, N. J.

sign to wait until it tended to approach the surface somewhere. This eventually occurred in about five days, when the patient was again etherized and a Kammerer incision made over the right lower rectus. The abscess was completely walled off and contained about four ounces of pus. It did not communicate with the former abscess and was on the right side of the mesentery. These cavities drained for about four weeks. The wounds had then healed completely and the patient was discharged from the hospital. After six months he was examined by me and no hernia was found in any of the scars, due probably to the fact that the first incision healed by first intention and the second and third were Kammerer incisions. He had some paralysis of the lower portion of the recti muscles, but otherwise was perfectly well. The button was never found, but an *x*-ray plate showed no evidence of its presence.

It is my opinion that the abscesses which formed were due to infection of catgut in the Lembert stitches. There was probably enough peritoneal infection thoroughly to contaminate the sutures, and they formed a nidus on either side of the mesentery. The fact that neither abscess contained fecal matter or had a fecal odor would seem to exclude any intestinal origin.

Case II.—The second case was treated on the surgical service of an institution in an adjoining State. The record reads as follows:

O. G., aged 32, German, carpenter. On the afternoon of admission the patient was engaged in sawing a piece of board with a circular saw, when for some unknown reason the board slipped and flew from the machine, striking him in the abdomen. The blow was quite severe and knocked the man down. He was taken to the hospital in a conscious condition and the only complaint was pain over the seat of the injury. He was found to be suffering from a moderate amount of shock, with pale face, and pulse somewhat accelerated. The abdomen showed a reddened area below and to the right of the umbilicus, this spot being very painful on palpation. There was considerable rigidity of the entire abdomen, almost equal, but a little more on the right side. The percussion note did not vary. The patient was catheterized and no blood was found in the urine. Examination of the heart, lungs, and extremities gave negative results.

The patient was put to bed and seemed to be quite comfortable. About seven o'clock the bowels moved slightly. He vomited at nine o'clock and was complaining of considerable pain over abdomen, this coming in paroxysms, and the patient sleeping in the intervals. At ten o'clock he voided apparently normal urine. The abdomen still remained rigid. At eleven o'clock he vomited again, so all mouth administration was stopped. White blood count taken at twelve o'clock normal. After this until morning the patient had a comfortable night.

The following morning the patient seemed to be resting quite comfortably. Examination elicited pain and tenderness over the seat of the injury; the rigidity of abdomen still persisted. Occasionally the patient would spit up mucus and at five o'clock the vomitus was fecal. White blood count at three o'clock 14,000. At five o'clock a well defined mass could be palpated in the right iliac fossa, and as a rupture of intestine was suspected patient was got ready for operation.

An incision five inches long was made in the median line below the umbilicus, the peritoneum was incised, and considerable bloody fluid escaped. Examination of the intestines showed them to be much congested and covered with considerable lymph. A small rupture about ¾ inch in diameter was found in the ileum; around this was considerable exudation, and patches of necrosis were found in the mesentery, where it was attached to the gut. Here and there on the gut were small patches of deep congestion. At the point of rupture considerable fecal matter was and had been coming through. The rupture was closed with double layers of Lembert sutures, black silk being used, the intestines were all cleaned off, put back, and the cavity well washed out with saline solution. The patient received about 500 c.c. of saline solution intravenously with other stimulation. A number of drains were left in and stitches were taken at the ends of the incision. The patient's condition was not very good, the pulse being very rapid and weak. The remainder of the night the patient was very restless, gradually growing weaker, and at nine o'clock the following morning he died.

I beg to call attention to the striking similarity of the conditions surrounding both cases up to the hour of interference. Here we have expressed in the line of treatment a marked difference of opinion. The boy referred to in the first case was operated upon in all possible haste after having been seen, whereas, in the second case it was thought best to defer operation twenty-five hours. Although the amount of injury in the former was much greater than that found in his unfortunate parallel, yet he is now about his work, whereas twenty-two hours of delay would in all human probability have allotted to him the fate of the other case referred to.

Injury to the intestines, including the stomach, without visible damage to the parietes is generally the result of some blunt force acting over an area of indefinite size. It is not necessary that the injury to the gut or its mesentery be in the immediate vicinity of the point of contact, as shown by cases where the rupture is at some distance. A blow just above the pubes may be followed by rupture of the stomach. This event is the exception. The abdomen need not be hit at all, as when laceration of the gut follows a fall upon the feet. The momentum acquired by the distended viscus is responsible for the damage, much in the same way as tearing of the liver and suspensory ligaments occurs as the result of a fall. The variety of accidents which may be to blame for such serious intestinal injury cannot be recounted in detail. Suffice it to mention that the most common are horse kick, falling from a height, being caught between cars, blows from fists, planks, shovels, etc. It is a curious fact that a blow upon a hernial tumor is not infrequently the history obtained (3 out of 21 cases). It is important to ascertain, if possible, the direction of the blow and the condition of the abdominal muscles. A contracted state of the abdominal muscles gives some protection to the viscera. Most of the cases of rupture are due to crushing of the gut against the bony structures, the spine of the ilium and brim of the pelvis, while a few are due to a bursting of the gut and others to traction. The wounds due to bursting are apt to be small, round, and jagged, whereas the crush cases show irregular tears. Traction cases seem to be associated more commonly with transverse rupture and laceration of the mesentery.

It is quite evident that in an ordinary case it is impossible to state just what combination of circumstances led to the injury. The condition of the alimentary canal must be an etiological factor of importance. To be sure, very few patients are ever asked just when they drank or ate last, but the time of injury is frequently given, as in 15 of the 21 cases upon which these remarks are based. Eighteen were in working men, and if we assume that the

average laborer eats at 6:30, 12 and 6 o'clock, the injury occurred in 12 cases within three hours of the last meal; in three cases more than three hours had elapsed, while in three cases the time was not given. The other three cases were in children. It is frequently claimed that distention with gas is a predisposing factor. This is theoretical, and if we are to theorize it would be more reasonable to assume that distention with fluids or semisolids is of greater importance. Fluids and semisolids are practically noncompressible and would have much more difficulty evading pressure than the gas. One need only remember that it takes but a comparatively slight blow upon the abdomen to cause the escape of flatus, whereas the escape of fæces following such moderate violence is certainly not a common accident.

As already indicated, males are far more frequently affected—only one female, and that a child of nine years, being among the 21 cases alluded to. Nearly 50 per cent. of the patients are between 20 and 50 years of age, and 50 per cent. of these between 30 and 40 years—these being the years of a man's greatest physical activity. Childhood is the age next in frequency.

The anatomical relations of the intestines are of etiological importance. The stomach and flexures are protected by the overlying thorax, whereas the rest of the intestine, with the exception of the rectum, is much exposed. The portion of the gut most frequently involved is the ilium, possibly because the contents are fluid and because of its exposed position in the center of the abdomen with the spine immediately behind. The jejunum is next most frequently injured, then follow the large intestine and duodenum. Fixation is of importance in the case of complete rupture which occurs most frequently in the region of the duodenojejunal angle.

Contusions may be of any degree, from those producing slight ecchymosis to those followed by extensive necrosis, and are dangerous when not operated upon because of the secondary perforation or hemorrhage. Most of the cases of secondary hemorrhage follow a contusion of the stomach. Hyperacidity and reduced functional activity of the bruised peritoneum in the region are factors of importance in this connection. Perforating rupture of the stomach is apt to be of the anterior wall and along the lesser curve and in some cases seems to be the result of very slight trauma.

Certain contusions of the intestines are followed by the formation of extensive hæmatomata. The effusion of blood is generally submucous and may be very extensive, forming large blood cysts. Incomplete ruptures may involve any combination of the three coats. When the mucosa alone is left intact, it protrudes sooner or later as a hernia, whereas the serosa when left does not remain long before perforating. Perforations of the gut are more common on the side opposite the mesenteric attachment. Small complete perforations may be plugged by the protruding mucosa and in this manner the escape of the intestinal contents prevented for some time. The contraction of the muscular coats of a completely torn-off piece of gut may temporarily close the lumen entirely. Rupture occasionally takes place in a retroperitoneal region of the intestine such as the posterior wall of the colon or duodenum—in which case extensive suppuration in the cellular tissue follows. It also happens occasionally that the escaped intestinal contents become walled off and give rise to a local peritonitis only.

Over 45 per cent. of the cases of injury to the intestine are combined with injury to some other intra-abdominal structure. Aside from the mesentary, the kidney is most frequently involved, then the liver and then the spleen. Other regions which may be involved are the omentum, mesocolon, a peritoneal fold, such as the gastrohepatic ligament, large vessels, pancreas, bladder, and bile-ducts. Several of these structures may be involved at the same time.

There is no individual symptom or any combination of symptoms always present which would allow us to make a diagnosis of rupture of the intestine, or even to determine in many cases whether the intestine had been injured at all. In a series of cases it will be found that shock, pain, nausea, vomiting, rigidity, tympany, regional dulness, and thoracic breathing are the symptoms most commonly found. Abdominal abrasions, hæmatoma, and lacerations of muscle may or may not be present.

When considering symptoms we must confine ourselves to those that occur in a case before any secondary condition such as peritonitis has complicated the picture, and as much as possible independently of symptoms and signs referable to other complicating injuries.

There is no means of standardizing shock unless we rely on the readings of the Riva-Rocci blood pressure apparatus, which have but a relative value. The amount present in a given case is measured solely according to the judgment of the surgeon in charge. During the first two hours the temperature rarely ranges higher than 101.5° to 102° and in cases with much shock and immoderate hemorrhage it may be subnormal. The pulse in an average case will not be over 100—again excepting extreme shock and hemorrhage. The expression is anxious, the skin is cool and covered with cold perspiration, the mucous membranes, tips of the ears, and the nose are blanched. The patient prefers to lie on his back, maybe with legs drawn up somewhat. The breathing is thoracic and somewhat increased, any motion of the trunk being carefully avoided. There are extreme cases in either direction, those with almost no symptoms at all, the patient having continued work or walked some distance before becoming aware of any unusual sensation; and there are those in which death occurs in a state of collapse within a few hours after the injury. The anatomical conditions may be identical in these extreme cases, so that it seems reasonable to conclude that the amount of concussion sustained by the abdominal nervous system is responsible for the variation in the clinical picture. The seat of an injury does not bear any relation to the amount of shock, neither does the amount of shock indicate the amount of damage to the gut. When the patient is seen after some time the symptoms due to shock may become continuous with those due to peritonitis.

Hemorrhage is present usually to a moderate degree, and in over 75 per cent. of the cases when the intestine alone is injured it is not sufficient to influence the symptom-complex. When the stomach is torn there is apt to be more hemorrhage. The conditions are quite different when the liver, spleen, kidney, pancreas, omentum, mesentery, mesocolon, or some other peritoneal ligament is torn. In these cases the symptoms of most importance may be those due to internal hemorrhage. There is at times quite a marked lack of proportion between the amount of blood found in the abdominal cavity on operation and the almost complete absence of symptoms (aside from dulness) suggesting an internal hemorrhage. It should also be remembered that the clinical picture of the most vicious type of peritonitis occurring within a few hours after rupture of the intestine, so-called "peritoneal septicæmia," resembles the symptom-complex of internal hemorrhage at times so

closely as to defy differentiation. Vomiting of blood occurs sooner the nearer the injury is to the stomach, but even when the stomach is injured vomiting may be absent or no blood may be found, only on microscopic examination. Blood could be passed immediately by the rectum only when the injury is in the lower part of the bowel. Dulness varying with position is due either to blood or to extravasated intestinal contents. When the amount of fluid is great, the intestines may be pushed up in the median line, and when they are somewhat distended they may partially cover up the liver dulness. Tympany is a symptom upon which great stress has been laid. It is pathognomonic when occurring in a circumscribed region at the highest point of the abdomen, and is due to gas outside the gut within the peritoneal cavity. Various surgical tricks have been played with this gas. One well known European surgeon passed a trocar and then ignited the escaping gas, a procedure that neither added useful data for diagnosis or increased the patient's chance for recovery. The injured man was extremely drunk. His overdistended stomach had been ruptured. Splashing sounds and the transmission of cardiac and respiratory murmur to the abdomen are signs of slight value. When the amount of gas within the peritoneal cavity is great or when the intestines are much distended, the liver dulness may be much diminished if not obliterated. This sign is quite uncommon in the early hours, and is either due to intestines and gas being interposed between the parietes and liver or to the liver being turned up, "on edge," as it were, presenting only its sharp margin for percussion.

Pain and tenderness may be present to any degree and may be local or general. Absence of pain proves nothing, and the presence does not indicate the kind of injury or enable one to differentiate between some evident complicating injury of the trunk and damage to the abdominal contents. In most of the cases seen early there is apt to be found an area where the pain and tenderness are greatest. Later on the secondary pain of a spreading peritonitis blurs the margin of this area. One must always be mindful of the treacherous cases where pain and tenderness are so slight as not to annoy the patient, especially when other evidence is scant. When pain is localized, it is generally referred to the immediate vicinity of the injury.

The degree of distention present immediately after the injury is due to the amount of gas within the intestines at the time of injury. Distention becomes more marked, however, very soon and may be due to increased accumulation of gas within the intestine or to gas within the peritoneal cavity combined with extravasation of blood and intestinal contents. When the injury to the intestine is high up, combined with a plugging of the opening by mucous membrane the segment proximal to the section of gut the motor function of which is interfered with, alone distends. This fact accounts for the absence of marked tympany and distention so common in injuries in this region. Several hours have generally elapsed before the case gets into the hands of a surgeon, which explains why the majority when seen in hospital practice show some distention. But even under these conditions there are cases in which the abdomen is perfectly normal in appearance, or even retracted. The duration of this state depends on the section of the bowel involved, the character of the injury, infection, and the gas-producing conditions of an individual case. Dulness indicates hemorrhage or the escape of intestinal contents. The dull regions may be both flanks and irregular patches throughout the abdomen. Vomiting is present in over half of the cases, and nausea is still more prevalent. The vomiting occurring immediately after the accident is reflex and due to the local damage to peritoneum and intestinal nervous apparatus. Few patients vomit immediately. The majority do not do so until after a few hours. In cases of perforation this is due to spreading peritoneal irritation. The late vomiting may also be due to intestinal obstruction. Even in cases in which the stomach is ruptured vomiting may be absent, as already mentioned, and in rupture of the duodenum vomiting of blood occurs in about half of the cases.

Rigidity is a sign of the greatest importance, of more importance than any other symptom because it is indicative of some severe injury to the peritoneum, whether traumatic or due to infection, but aside from this it does not tell what the character of the damage may be. In one case there may be simply a contusion of the abdominal wall with very marked rigidity, while in another with little rigidity there may be a rupture of the gut. Cases without any rigidity and resistance are uncommon. Pressure increases the resistance. The rigidity is not necessarily uniform; on the contrary, in the early cases one may find some area as a rule where it is most marked. The diffuse uniform rigidity of general peritonitis is quite different. The cremaster muscle is said to partake of the early contraction. Emphysema of the abdominal wall is a symptom occasionally observed in retroperitoneal injuries and when the abdominal wall has been injured on the inner side.

It is impossible to make an absolute diagnosis of the exact intra-abdominal conditions. A probable diagnosis is the best we can make. It is not generally possible to rule out injury to liver, spleen or pancreas, and frequently it is not possible to exclude injury to the kidneys. Although a complicating injury to the bladder may be impossible to detect, still a complete rupture is apt to be indicated by a pretty distinct symptomatology. It is at times impossible to state whether the condition of the patient is not due to a contusion of the abdomen alone. The hemorrhage from a liver is at first confined to the right side, and that from the spleen to the left, going into the pelvis. Pain in the shoulder and an increase of urobilin in the urine are in favor of liver injury, while pain in the left shoulder and a change in the quality of the voice may be present with injury to the spleen (right vagus—splenic plexus). The positive signs of injury to the kidney are well known. It is a dangerous procedure to give a patient much to drink after an injury, as is done at times to elicit reflex vomiting in cases of injury to the stomach. Provided the stomach is injured no particular good can come from washing the stomach contents into the peritoneal cavity. The same applies to enemata. The sluggish peristalsis of the large intestine combined with the character of the contents, and maybe plugging of the opening by mucous membrane, give an individual a certain amount of protection until he receives aid. There is no particular point in breaking down even this slight protection by washing the contents of the sigmoid through the wound of the gut. Such diagnostic measures are dangerous.

We should not neglect to examine the spine, especially when the history is that of a fall. Rigidity of the parietes, pain in the abdomen, and almost no deformity of the spine may lead to an embarrassing error awkward to explain.

The question which presents itself to the practical man is: Has the patient sustained any injury to his abdominal contents? Where there is shock, rigidity,

pain, vomiting, perhaps of blood, or bloody stools, abnormal dulness, and areas of tympany, the question is easily settled. In many cases we have no such clear picture and we are faced at once by the second question—how much must a man injured show to justify an exploratory laparotomy to determine what has happened?

Personally I am of the opinion that with a history of trauma, a patient need only have moderate rigidity of his parietes to justify interference. If he has pain, vomiting, and the rest of the symptoms common in an average case, then it is easier to decide, even if the symptoms and signs are but slight.

Given an individual with rigidity and not much else, a quick exploratory operation is practically devoid of risk. If a rupture is found, no better condition could be asked. If we wait till secondary signs of peritonitis or a secondary hemorrhage makes it clear beyond doubt that an intra-abdominal injury has occurred, then we have missed the golden moment and must operate when the patient's chances are incomparably worse. Every minute is valuable, for the number of cases recovering after a wait of twelve hours is exceedingly small. The cases in which the symptoms of abdominal injury are well marked may be subdivided into three classes: those with average symptoms, those with excessive shock, and those moribund when first seen.

The first class with average condition, we stimulate and operate on immediately; those moribund we let alone, and those with excessive shock constitute the only cases in which a moderate wait is justifiable. Here we make an endeavor to overcome the shock, as much as possible, with saline infusion, heat, stimulants, auto-infusion and Cryle's shock jacket, and try to bring the condition to the point where a patient may stand the additional shock of surgical interference. The moment for interfering is hard to choose and no general rules can be laid down. The conditions of the individual case rule, as well as the individual surgeon's sense of proportion between what he thinks he may be called upon to do and the patient's condition.

It is difficult to decide at times whether the continued shock is due to lack of reaction on the part of the patient or whether it is due to hemorrhage, or when it occurs still later, perhaps to peritonitis. A rising pulse and falling temperature are, of course, strongly in favor of the former; whereas a rise in temperature with increasing local signs will incline us towards the latter.

So far as the operation itself is concerned the main thing is to get through quickly, but without haste. Everything should be ready before the anæsthetic is started. Infusion apparatus, stimulants and heaters; the surgeon should be washed. If there is local pain or some sign or symptom that attracts us to a particular region, it is well to make the incision in this area, otherwise a median incision, or rather one a little to one side of the median line in the vicinity of the center of the abdomen, will be preferable. One can then enlarge in any direction. Blood and intestinal contents furnish us the trail. If excessive we wash out with a large tube—one with a return flow arrangement is an unnecessary refinement. The fluids are usually not accommodating enough to take this prescribed return route. One essential is to have a tube which will furnish a stream about the size of an index finger. We waste no time then. To wipe out the abdomen with dry gauze sponges is objectionable, for it injures the peritoneum, and experiments on animals have demonstrated that this greatly diminishes the functional activity of this structure. Small holes in the intestine are closed according to their conformation—longitudinal, transverse, or puckered. I prefer silk for my first suture and bring the peritoneum over with catgut. If there are several rents near together, it may be quicker to resect. Whether a button or a suture is used depends on the condition of the patient, the custom of the operator, and the region operated upon. Buttons may be used in the small intestine. Sutures in the stomach, duodenum, and large intestine. If there is a large pear-shaped hæmatoma of the mesentery, or if the mesentery is torn extensively from the gut, it is best to resect.

The duodenum is difficult to close, especially if the retroperitoneal region is torn or the vicinity of the ampulla of Vater is damaged. Injury to other viscera will have to be treated according to circumstances. The absence of blood and intestinal contents does not exclude a perforating injury—the opening may be plugged for the time being, as already mentioned. Because of this and because of the contusions, it does not do simply to open the abdomen, and on finding no blood, close up again. Contusions should be carefully sought for and turned in with Lembert sutures. It should also be remembered that complete lacerations are frequently multiple. It is an advantage to sew a piece of omentum down over the suture line, so that in case of infection we favor walling off. Provided there is no injury to some other viscera demanding drainage, and provided we are reasonably sure of our junction, it is my opinion that the abdomen should be closed tight. Drainage may be used when we close a piece of intestine not entirely covered with peritoneum, or when we have opened into an extensive peritonitis.

Any structure with sufficient circulation does not yield readily to infection. The peritoneum is well supplied and its cells are perfectly able to take care of a number of bacteria. It will even digest to some extent and remove blood clots and other material. When there are sloughs, large pieces of fibrin, or pieces of intestinal contents left behind, these form a good medium for bacteria. The peritoneum is powerless, its only efforts being to wall off the offending material if possible by adhering about and diminishing peristalsis in this region. When, therefore, there is no dead material left behind and no extensive peritonitis, we prefer to close the wound, after careful washing, with salt solution. A moderate local peritonitis is no contraindication. I prefer to use opium in small doses after these comparatively clean operations. The peritoneum has about the same number of square inches as the skin. There is in all perforating injuries some infection in one or more of the five main pouches. If we give cathartics we increase the motion of the intestines and favor a spreading of the virus from one place to another. The intestines are "kept on the move," as it were. To be sure, cathartics do somewhat increase the functional activity of the peritoneum, but the increase in the region infected does not offset the damage done by favoring a spreading of the bacteria; neither does opium, in keeping the intestines quiet, abolish its activity. This does not apply where the amount of infection is great to start with. Here we have passed the stage of spreading the virus, the peritoneum is extensively damaged, and the aid we derive from cathartics offsets any disadvantage due to stirring up the immediate vicinity of the wound.

If we have operated on a leg we use a splint, and opium in small doses, to my mind, is a good splint for the intestines. During the first week, in accord-

ance with the idea of resting the wound, we give but little in the way of liquids by the mouth, and rely chiefly on rectal feeding, provided this section of the bowel is not involved. When there is much distention of the gut due to gas, we are forced to meet this with a cathartic.

The prognosis depends greatly upon the time of operation. The average wait before operation in the six cases which recovered was 8½ hours, while the corresponding time in nine fatal cases was 22½ hours, which clearly indicates that the earlier the operation the greater the chance of recovery. Injuries to the stomach and large intestine have a better prognosis than injuries to the small intestine, possibly because the stomach contains comparatively few bacteria, or because the colon's sluggish peristalsis and solid contents do not hasten peritoneal infection. The prognosis of rupture of the duodenum is bad, partly because the gut is not entirely covered by peritoneum, and partly because of complications referable to the ampulla of Vater, bile-ducts, or pancreas. Complications present must effect the final results according to their nature. Cases not operated upon are hopeless, and if all sorts of cases be considered the death rate will be found to be between 75 and 80 per cent.

To summarize tersely we may say:

1. Any injury to the abdomen may be associated with damage to the intestine or other viscera.
2. An exploratory operation is justifiable in cases with distinct rigidity.
3. An operation is absolutely indicated when there is, besides rigidity, pain, tenderness, vomiting, shock, dullness, or other symptoms indicative of some intra-abdominal disturbance.
4. Cases not operated upon are lost.
5. The importance of early operation cannot be emphasized too strongly.
6. At present the death rate is about 75 to 80 per cent.
7. When a greater proportion are operated upon early, the death rate will be much lower.

COLD FRESH AIR TREATMENT OF PNEUMONIA IN INFANTS AND CHILDREN.

By W. P. NORTHRUP, M.D.,
NEW YORK.
PROFESSOR OF PEDIATRICS IN THE UNIVERSITY AND BELLEVUE HOSPITAL MEDICAL COLLEGE ATTENDING PHYSICIAN TO PRESBYTERIAN AND FOUNDLING HOSPITALS, CONSULTING TO WILLARD PARKER AND RIVERSIDE HOSPITALS, N. Y.

As the fresh air treatment of acute infectious diseases with marked toxemia, fever, and prostration is so much before the professional mind just now, I beg to submit report of two cases bearing directly on the point. I believe it is about to become the fashion to treat pneumonia more on hygienic lines, and to rely largely on the supporting power of cold fresh air.

In the treatment of a case of pneumonia in a child in a Hudson River town, I had the windows of the sick room taken out and cheesecloth put in their places. Besides that, an electric fan drew the air from the room into the hall, in order to ensure a free inflow of outdoor air at the windows. The month was March, and very dusty, hence the cheesecloth. This was not a robust hospital man, but a marantic baby, a poor little thin, pale thing. It was no baby to experiment with, from a physical or social standpoint. How to give this scrap of mortality a chance to live through its pneumonia was the only question, and I was to answer it. My convictions were sufficiently strong, and I followed them. Recovery was perfect.

Incidentally I may mention that the town was soon informed that the poor little baby, the mayor's child, was dead. Poor thing! The bedding, it was said, was airing from the back windows! This rumor was contradicted, and the news circulated again that this was only the method of a crank doctor from town, and to the surprise of all the baby got well.

Someone asked—Now would you treat your best family patient thus? Can you get people to allow you to let cold flowing air in upon the patient acknowledged to be suffering from pneumonia? Have you the courage to air them thoroughly?

I submit in answer the history of the following case, which has been reported previously, in an address delivered at a joint meeting of the Chicago Medical Society, and the Chicago Pediatric Society (*Chicago Medical Recorder*, for November, 1904). It was far from being a hospital case. The father and grandfather, and other members of the family were all total strangers to me, the infant was the one offspring of young, anxious parents, but both parents were sensible. The force of this word will be appreciated as I proceed.

The history of the case was as follows: female, fourteen months. It had had rickets and scurvy, could not make the first effort at walking. Its legs hung down like empty stockings. It had a well marked rickety rosary and prominent abdomen. Its general appearance, however, was that of a "pot bellied," feeble, perspiring child, with much curly hair; in coloring, in the fairness of skin, with delicate touches of rose in the lips and occasionally in the cheeks, in darkness of eyes and hair it was a beautiful child. Even one less near to it than fond young parents, doting grandparents, and loving aunts, of which it had a full quota, could not help feeling a strong attraction.

The diagnosis was bronchopneumonia. Pulse, 180-140; respiration, 60-40; temperature, 105°, delirium. One would not call this a mild case.

On my first visit I told the parents frankly that the lungs were the part affected, that it would be pneumonia probably, that it would run a course of five to twelve days, would terminate in recovery. That was the rule in cases of primary pneumonia, and though the patient was very young and not very strong, I hoped and expected it would do just as I had said.

I may confide to the reader that I had anxieties unconfessed, and that my external appearance of hopefulness and confidence was partly born of a desire to be kind, and to allay their fears. Frankly, I considered the child hardly a first-class risk, and had my own anxieties the whole time. At any rate I proposed to give one night's sleep to the household before laying down my verdict that it was surely pneumonia.

At my visit on the following morning, I confessed the whole truth, that it was pneumonia, that I had individual ideas as to the care of pneumonia patients, and I wished to talk it over with the father and mother. I told them that the one thing which would help the anemic little one to bear her poison, eliminate it, redden her blood, and sustain her heart, was cool, flowing fresh air, day and night. I said the child had a sore lung, a limping respiration, diminished breath room, that to air its blood it had to pant, and panting was hard for the heart. To be kind to the patient, we must give her oxygen-full air, not second-hand breaths. She must not be made to breathe five time where three would do. "If your wife fainted in a theater," I added, "you would not gather a crowd about her, and shut the doors and windows? If her heart failed because the bad air had saturated her blood and smothered her, you would not suffocate her more? You would

face her into the cool, flowing fresh air, you would wet her brow and moisten her lips with cool, fresh water, you would refresh, refresh, refresh. In other words, you would stimulate her heart with cool fresh air, and cool fresh water.

"The child," I said, "could not catch cold from air touching her face. The dry skin of a fever patient was not susceptible to cold. A fever patient in bed was quite safe. Cool, fresh air reddens the blood, stimulates the heart, quiets restlessness, favors sleep, improves secretions and digestion, in short, meets most of the indications for treatment of pneumonia in infants."

I then descanted upon the need of water, inside and out. I told the parents that water dilutes and cools the body fluids, washes the blood and pores and kidneys, favors elimination of poison, and refreshes the system. Externally it cools the temples, moistens the lips, quiets the nervous agitation induced by hot, dry skin and mouth. Further, since I was not exhibiting any medicine, I explained about the use of hot foot baths. "If the feet are cold, ten chances to one," I said, "the head is hot, the face flushed, perhaps dusky. There is a disturbance of the blood tide, the tide has set toward the head; the lungs, face, and brain are flushed, and nervous restlessness or stupor or delirium is the result. The indications are obviously to distribute the congested blood, to draw the blood down into the feet, and away from the brain and head. The foot bath does it best. I know no drug so good."

I watched the faces of my new-found friends, and went on explaining, and ended by saying, "All I can add is, that if that child were my own, I would give it air, air and water." Then I waited. The parents had German blood. Their parents were born where the night air was made to be shut out. After a single moment's reflection these anxious parents made this answer: "What you would do for your own, that's what we want you to do for ours."

From that day on the parents were almost silent. They kept from offering suggestions, meddling in any way, or asking any questions. They simply came to the door as I went out, and with a furtive gripping of each other's hands, they waited in suspense my report. Nothing more.

The largest room practicable in the house was selected, the crib was placed near the middle wall opposite the two windows and two doors; one window and one or two doors were constantly open. The month was December, and the weather was exceptionally cold. The windows were open night and day, and one night the thermometer in the room reached 28° F. In compassion for the nurses the friends of the family produced two automobile fur coats, which they wore night and day. I seldom removed my overcoat in visiting the patient. One of the many friends of the family, I was told afterwards, on coming into the house exclaimed, "Ugh! Where's that cold? Pneumonia too? Well, all I've got to say is, that if I had too large a family and wanted to get rid of them quick, I'd do that." How about the patient? She was fired to an internal heat of 105°. Her pretty little face was bathed by cool, flowing air, and she slept. If, by reason of necessary exposure, the windows and doors were closed temporarily, she showed restlessness, which disappeared when the windows were again opened.

There were two tendencies of the case—one to become flatulent and distended, the other to have cold feet. Each time either condition prevailed the face became dusky, restlessness was marked, and at times there was delirium. For these two conditions the sovereign remedies were the foot bath and high hot saline injections. For heart stimulant, a hot foot bath; for flatulence, a hot, high saline injection; for restlessness, either or both of these. These two afforded relief, followed by three hours of sleep. In giving the foot baths, the child was elevated on a firm pillow, and the feet were let down into a basin under the bed covers, hot water was added a little at a time, with constant friction of the feet. The action of these two derivatives, hot foot baths and hot high salines, was enough to remove all untoward symptoms.

The case ran a course of twelve days, recovery taking place by crisis. The best is yet to be mentioned. The digestion in this case had given great trouble. At the onset of the pneumonia there was diarrhea with green mucous stools. The toxins of pneumonia disturbed the digestion still further, and the tendency to flatulent distention was marked. It was a constant problem to find anything which would be digested. But as soon as the crisis had passed and the fever was gone, the child simply opened her eyes, smiled, and began to digest her food as though nothing had happened. She was a trifle pale and rather weak, but a less damaged baby I have never seen. Here is a striking illustration of the peculiar feature that the disturbance of intestinal digestion ceases with the ending of high fever.

After the first twenty-four hours the parents were satisfied with the treatment and my explanations. Nothing more was said until the temperature had been normal for twenty-four hours. The tension was then past, and for the first time, you know how it is, all began to talk. I asked the nurses what they thought of the fresh-air treatment for pneumonia, and they confessed that at first they were horrified, and thought they themselves would catch cold and get sick. To their relief they soon found that they endured their vigils much better, were fresher and wider awake from having constant good air. They were truly delighted. They declared that my prognosis was fully justified and believed that the patient passed through with less exhaustion than any other they had ever known.

This point I wish to reiterate: This feeble child passed through her serious infectious disease with less injury to her general nervous system than any other I have known.
